Royal Society, February 5.—H. M. **Carleton**: Growth, phagocytosis and other phenomena in tissue cultures of fœtal and adult lung. Invasion of the medium in a growing culture is the result of:—(1) Sheet-like epithelial outgrowth from the alveolar epithelium of cut alveoli. (2) Radiating growth of fibroblasts from the connective tissue of the lung. (3) "Membrane-formation," in which the cells of the cicatricial epithelium detach themselves from the implant. Within the implant there occurs a swelling up, and a detachment of, the alveolar epithelial cells. Mitoses are frequent in these—even in cultures of adult lung. Sterile coal or carmine particles are actively phagocytosed by both fœtal and adult lung *in vitro*. The alveolar epithelial cells are actively phagocytic, the dedifferentiated cells of the cicatricial epithelium less so.—F. W. **Fox** and J. A. **Gardner**: The origin and destiny of cholesterol in the animal organism. Part XIV.—The cholesterol metabolism in normal breast-fed infants. During the first week of life there is a daily average negative balance of 0·14 gram. This is to a large extent accounted for by the fact that the meconium is being got rid of. During the second and third week of life the average intake and output in the cases examined practically balance. At this stage the composition of the milk is in a transitional state from colostrum to true milk. In the last group of infants, from the seventh week to tenth month, there is an excess of intake over output, and the average positive balance is 0·069 gram per day. There must be some organ in the body capable of synthesising cholesterol, but the sterol present in the diet of infants is a source of supply which cannot be disregarded.—H. H. **Thomas**: The Caytoniales, a new group of angiospermous plants from the Jurassic rocks of Yorkshire. The fossils are the remains of megasporophylls with carpels, fruits, and seeds of two distinct types, and male inflorescences bearing stamens. They were found in the Gristhorpe Plant Bed in the Middle Estuarine Series, exposed on the Yorkshire coast in Cayton and Gristhorpe Bays. The species *Gristhorpia Nathorsti* gen. et sp. nov. had pinnate megasporophylls 4-5 cm. long, with an axis about 1 mm. wide, the sub-opposite pinnæ terminate in small more or less spherical carpels 2-5 mm. in diameter. The carpels have a stigma at the base near the pedicel. Winged pollen-grains were found on some of the stigmas. The seeds had a well-developed megaspore membrane with an apical projection, above which was a micropyle lined with cutinised cells. *Caytonia Sewardi* possessed megasporophylls agreeing generally with those of Gristhorpia, but the stigma was a small basal flange. The carpels and fruits contained two rows of ovules or seeds, with hard woody or stony testas. The remains of the male inflorescences are of a type previously known as *Antholithus* sp. and now named *Antholithus Arberi*. They were probably borne on the same plants as *Gristhorpia Nathorsti*. The anthers were four-lobed sessile structures, of a form very like that found in many modern Angiosperms, and had a longitudinal dehiscence. There are no traces of perianth members or bracts. There is a constant association of megasporophylls and fruits with leaves of *Sagenopteris Phillipsi* (Brongn.). The comparative examination of the cuticular structure of the axes of Gristhorpia and Caytonia and of the petioles of Sagenopteris fronds, makes it probable that Sagenopteris must be regarded as the leaf of the Caytoniales.—Winifred **Brenchley** and H. G. **Thornton**: The relation between the development, structure and functioning of the nodules on *Vicia Faba* as influenced by the presence or absence of boron in the nutrient medium. In the absence of boron the vascular supply of the nodule is defective. The strands are often entirely absent, or weakly developed. In plants grown without boron the number of nodules that attain macroscopic size is much reduced. In the nodules without vascular strands, the bacteria do not swell out to form the so-called "bacteroids." When weakly developed strands enter the nodule, the amount of tissue containing bacteroids is closely correlated with the extent of the strands. In the plants bearing these abnormal nodules very little nitrogen is fixed, the quantity fixed per nodule being, in one experiment, less than one-tenth of that fixed in normal plants. In the absence or weak development of vascular strands in the nodule, the bacteria tend to become parasitic. This change in relations between micro-organism and host is connected with loss or reduced supply of carbohydrate energy material normally brought into the nodule by the vascular strands.—A. S. **Rau**, F. W. R. **Brambell** and J. B. **Gatenby**: Observations on the Golgi bodies in the living cell. The so-called "nebenkern" of molluscan germ-cells is the Golgi apparatus, and it can be shown *intra vitam* by Janus green and neutral red. It is visible in fresh cells *intra vitam*, and can be photographed. It stains heavily in the Lewis Janus green-iodine vapour method. The Golgi rods or batonettes are rigid bodies, which retain their shape when released from the cell. Neither the Lewis Janus green-iodine vapour method nor Janus green alone are specific for the mitochondria.—V. **Nath**: Cell inclusions in the oogenesis of scorpions. In forms the oocytes of which contain vitelline yolk there is copious discharge of nucleolar material preceding yolk formation. In other forms the nucleolus remains quite inactive. The Golgi elements in Palamnæus swell up enormously after fragmentation and give rise to yolk (Golgi yolk), which contains free fat like the Golgi yolk of Lithobius (Nath) and *Helix aspersa* (Brambell). The Golgi elements of Euscorpius and Buthus also swell up and form Golgi yolk which, however, retains the same chemical constitution as the Golgi elements. In the centrifuged oocytes of Euscorpius the vitelline yolk is thrown down and the Golgi yolk tends to go towards the opposite pole. The central area is occupied by the granular mitochondria, the unchanged Golgi elements and the nucleus. The mitochondria in all the forms studied are granular and do not take any part in vitellogenesis. Although there is a remarkable disparity, paralleled only in *Paludina vivipara*, in size of the granular mitochondria of oocytes, on one hand, and the very prominent, hollow, vesicular mitochondria of spermatocytes on the other, the vesicular type is only a phase in spermatogenesis.—L. J. **Harris**: The combination of proteins, amino-acids, etc., with acids and alkalis and their combining weights, as determined by physico-chemical measurements.

Physical Society, January 23.—W. **Clack**: An investigation into corrections involved in the measurement of small differences in refractive index of dispersive media by means of the Rayleigh interferometer, with special reference to the application of the results to measurements in diffusion.—B. J. **Taylor** and W. **Clarkson**: A study of the production of "flashing" in air electric discharge tubes. The volt-ampere characteristics for the air discharge tubes is of the general form, $i = k(V - M)$. As in the case of the

"osglim" lamp, there is a critical resistance R_c below which no "flashing" is possible, given by $R_c = E - V_a/\{k(V_a - V_c)\}$.—C. R. **Darling**: A kinematographic study of the formation of Plateau's spherule. Orthotoluidine is allowed to flow slowly into the bulb of an inverted thistle funnel supported mouth downwards in water; when a sufficient body of the liquid has collected, a large drop is formed which gradually changes shape until it breaks away, leaving behind a small secondary droplet known as "Plateau's spherule." Kinematographic study of the breaking process shows that the main drop remains approximately spherical, the liquid to which it is attached extending downwards in a sharply pointed cone attached to the main drop at its point. After breaking away, the main drop falls, oscillating considerably in shape. The rest of the liquid snaps back to form a more or less spherical surface, but the point of the cone is left behind to form the droplet referred to; this is given a slight upward impulse before it also falls to the bottom of the water.

PARIS

Academy of Sciences, December 29.—Ch. **Lallemand**: Concerning the tetrahedral system. Lowthian Green in 1875 suggested that a hollow sphere, submitted to an external pressure, should take a form derived from the tetrahedron. In a recent note Lecornu shows that this view is not supported by a mathematical investigation. Experiments by the author, in 1887, on rubber balloons, and by Ghesquière and de Joly, in 1895, on glass globes softened by heat, are in accord with the tetrahedral theory.—Marcel **Brillouin**: The equations of state of the plastic phase of a solid naturally isotropic.—Gabriel **Bertrand** and M. **Mokragnatz**: The general presence of nickel and cobalt in arable earth. In an earlier communication, the presence of traces of nickel and cobalt in two samples of soil was proved. The analytical method has now been improved, and results of analyses of thirty-three soils from different localities (France, Germany, Denmark, Italy, Roumania) are given. The amounts found, expressed in parts per million of earth, vary between 38·6 and 4·7 for nickel and 11·7 and 0·3 for cobalt. There is always less cobalt than nickel. Dust from interplanetary space is suggested as a possible source of these two metals in arable earth.—André **Blondel**: Certain coefficients of self-induction of alternators.—V. **Grignard** and J. **Savard**: The enolic form of pulegone.—C. **Sauvageau**: Some examples of *hétéroblastie* in the development of some Algæ (Castagnea).—R. H. **Germay**: The integration by successive approximations of systems of partial differential equations of the first order.—Fritz **Carlson**: Integral functions.—S. **Stoilow**: An ensemble where a continued function has a constant value.—Antoine **Lomnicki**: Some generalisations of the arithmetical triangle of Pascal.—L. **Escande** and M. **Ricaud**: Some methods of measuring velocities in hydraulics. The chronophotographic method of measuring velocities, utilising fine powder in suspension, fails when the fluid is in a turbulent state. The substitution of small spheres of density equal to that of the water for the powder gives good results for the mean local velocity. The conditions under which the Pitot tube gives trustworthy measurements are discussed, and a modified method suitable for low velocities described.——**Rateau**: Remarks on the preceding communication.—A. de **Gramont de Guiche**: An acoustic indicator of relative velocity for an aeroplane.—R. **Biquard** and A. **Chenu**: A method for the regeneration of the gas of a balloon, avoiding deflation.—J. **Guillaume**: Observations of the sun, made at the Observatory of Lyons during the third quarter of 1924. Observations of the number of spots, their distribution in latitude, and the distribution of the faculæ in latitude were made on 87 days during the quarter.—A. P. **Rollet**: An electrolytic frequency meter of simple construction. The apparatus is based on the phenomena of successive oxidation and reduction shown by a silver electrode, when the electrolysis takes place in an alkaline solution with a low frequency alternating current.—Albert **Nodon**: Researches on X-rays of long wavelength.—J. H. **Shaxby**: The production of Laue diagrams by means of monochromatic X-rays, and the structure of mother-of-pearl. The mineral part of mother-of-pearl consists of crystals of aragonite, the quasi-hexagonal axis of which is normal to the leaflets.—F. **Croze**. The structure of the line spectrum of nitrogen.——**Lespieau**: The preparation of true acetylene compounds, starting with the mixed magnesium derivatives of acetylene.—H. **Colin** and Mlle. A. **Chaudun**: The hydrolysis constant of sugar. The authors qualitatively confirm the results of Moran and Lewis, and find that the velocity of hydrolysis increases more rapidly than the concentration of the sugar, although quantitatively there is not exact agreement. This increase in the velocity of hydrolysis with sugar concentration is shown to depend on the nature of the acid employed as the catalyst.——**Royer**: The orientation of the crystals of ammonium iodide by muscovite.—G. **Mouret**: The structure of the granitic region of Millevache.—Maurice **Collignon**: The audition of explosion waves at great distances. Deductions from the explosion experiments at Courtine in May 1924.—M. **Coyecque** and Ph. **Wehrlé**: The formations of Hatteras.—Paul **Guérin**: The development of the anther and pollen in gentians.—L. **Léger**: The nutritive value of the snail (*Helix pomatia*). In *Helix pomatia*, in the condition of winter sleep, upwards of 80 per cent. of the fat, and all the glycogen and reducing sugars, are localised in the part usually rejected for food. The snail should be eaten *in toto*.—Alexandre **Lipschütz**: An intersexual malformation in the guinea-pig.—Léon **Blum**, Maurice **Delaville**, and van **Caulaert**: Contribution to the study of the pathogeny of rickets. The essential trouble in rickets is not due to an alteration of the mineral contents of the blood, but in modifications of their physico-chemical state, the latter resulting from an alteration of the acid-base equilibrium.—Marcel **Duval**: The ionic reaction of the blood of some invertebrates.——**Cluzet, Rochaix** and **Kofman**: Variations in the agglutinating power of sera under the influence of the continuous electrical current.—Maurice **Nicloux**: New demonstrations of the normal presence of carbon monoxide in the blood. The presence of traces of carbon monoxide in normal blood has been disputed: from the results of experiments described by the author, the presence of this gas in normal blood is proved.—A. **Malaquin**: The genital glands and primordial sexual cells in the annelid *Salmacina Dysteri*.—Mlle. **Goldsmith**: Light and the symbiotic relations in *Convoluta roscoffensis*.—Constantin **Gorini**: The mammary coccus.—A. **Borrel** and Mlle. **Muller**: Vaccinal virus in the cornea of the rabbit.

January 5.—L. **Lecornu**: The tetrahedral deformation. Remarks on the experiments of M. Lallemand.—W. **Kilian** and G. **Sayn**: The external edge of the subalpine chains to the east of Valence (Drôme) and the breccia of Pialoux.—Paul **Vuillemin**: The *Nématés*, a new division of the animal kingdom.—Jean **Effront**: The absorbing power of agar-agar. Extraction with acid reduces the mineral content of agar-agar, and this demineralised agar does not absorb acid. Pulps from plants, such as beetroot and potato, behave in a similar manner.——**Angelesco**: Certain systems of

biorthogonal functions.—A. **Bloch**: On a circle where a holomorph function takes at least twice the values 0 and 1.—S. **Saks**: A class of interval functions.—J. **Haag**: The experimental determination of the parameter of precision.—A. **Talon**: The piezometric equivalence of the yield of transmission.—W. W. **Heinrich**: New classes of secular solutions of the problem of n bodies.—L. **d'Azambuja**. Observations of mobile masses of absorbing vapour at great heights above the solar surface. Comparison with high protuberances of rapid evolution.—Albert **Pérard**: The refractive index of air, in the visible spectrum, between 0° and 100° C. The apparatus used was that of Benoit, slightly modified. The final result is given by the equation

$$(N-1)10^6 = \left(288{\cdot}02 + \frac{1{\cdot}482}{\lambda^2} + \frac{0{\cdot}0309}{\lambda^4}\right)\left(\frac{h}{760}\right)\left(\frac{1}{1+0{\cdot}003716\,\theta}\right),$$

where λ is the wave-length in microns, θ the temperature in centigrade degrees.—Y. **Rocard**. The diffusion of light in fluids.—Mlle M. **Hanot**: The width of the lines of the Balmer series in the oscillating discharge. For a given initial temperature and pressure, the maximum intensity of the current which traverses a slightly damped oscillating spark determines the width of the lines studied.——**Bayen**: The spark spectra of tungsten and mercury in the extreme ultra-violet.—R. **Jouaust** and P. **Waguet**: The use of the photo-electric cell for certain measurements in industrial photometry. In photometric measurements it is not, in general, possible to replace eye observations by a photo-electric cell, but in certain cases it is possible. One possible application of the cell is the preparation of standard electric lamps, and a description of the method used and precautions necessary is given.—J. **Valentin** and G. **Chaudron**: The solidification of the ternary alloys of aluminium, magnesium, and cadmium.—Édouard **Urbain**: The absorption of vapours by carbon. Defining the "compacity" of carbon as the ratio of the true volume to the apparent volume, absorption curves are given showing the amount of vapours of chlorine, chloropicrin, and benzene absorbed as a function of the compacity. In the case of benzene there is a maximum absorption for compacity 0·3.—Pierre **Auger**: The secondary β-rays produced in a gas by X-rays.—L. **Hackspill** and R. **Grandadam**. The displacement of the alkali metals by iron. At a moderately high temperature, in a vacuum, iron sets free the metals of the alkalies from their hydroxides; in some cases it is possible to collect the alkali metal, in others the presence of the metal can only be proved by the evolution of hydrogen in contact with steam.—Al. **Orékhoff** and Max **Roger**: The semipinacolic deamination of some amino-alcohols. Amino-alcohols of the type $R.R'.C(OH).CH_2(NH_2)$, treated with nitrous acid, give the ketones $R.CO.CH_2.R'$.—Max and Michel **Polonovski**: Oxyeserine and its derivatives.—Marcel **Sommelet**: Researches in the diphenylmethene series. Trimethylbenzhydryl-ammonium bromide.—J. **Grosjean** and M. **Dosios**: The horizon of the Posidonomyes schists containing hydrocarbons of the Toarcian of the Franche-Comté Jura. Analyses of four schists are given, showing yields of oil. Separate analyses of the oils are appended.—E. G. **Mariolopoulos**: The rains sometimes observed with anticyclones.—René **Fabre**: The nature and variations of the aldehyde contained in the blood. There exists in the blood a volatile reducing substance possessing the characters of acetaldehyde.—G. **Mouriquand**, A. **Leulier** and P. **Michel**: Fluctuations of the iron in blood in the course of experimental scurvy.

Diary of Societies.

SATURDAY, FEBRUARY 14

ROYAL INSTITUTION, at 3.—W. Rothenstein: The Artist's Relation to Social and Religious Life (I.).

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 4.—Sir D'Arcy Power: Hunterian Oration.

INSTITUTION OF STRUCTURAL ENGINEERS (Western Counties Branch) (at Royal Institution, Swansea), at 6.—G. B. R. Pimm: Piles and Pile Foundations.

INSTITUTE OF BRITISH FOUNDRYMEN (Lancashire Branch, Junior Section) (at Municipal College of Technology, Manchester), at 7.—W. H. Meadowcroft: Some Foundry Experiences.

INSTITUTION OF AUTOMOBILE ENGINEERS (at Loughborough Technical College), at 7.10.—Loughborough Graduates' Meeting.

INSTITUTE OF METALS (London Local Section) (at Institute of Marine Engineers), at 7.30.—V. C. Faulkner: Some Notes on Refractory Materials.

MONDAY, FEBRUARY 16

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—C. P. G. Wakeley: The Etiology, Pathology, and Treatment of Ectopic and Imperfect Descent of the Testis.

ROYAL SOCIETY OF MEDICINE, at 5.30.—Dr. L. Williams, Col. R. McCarrison, Dr. W. Cramer, Dr. G. M. Findlay, and others: Special Discussion on Non-Specific Disturbances of Health due to Vitamin Deficiency.

INSTITUTION OF AUTOMOBILE ENGINEERS (Birmingham Centre) (at Chamber of Commerce, Birmingham), at 7.—F. G. Woollard: British Methods of Continuous Production.

JUNIOR INSTITUTION OF ENGINEERS (North-Western Section) (at 16 St. Mary's Parsonage, Manchester), at 7.15.—A. D. Young: The Design and Construction of the No. 5 Gas Holder for Burnley Corporation.

INSTITUTION OF AUTOMOBILE ENGINEERS (Scotland Centre) (at Royal Technical College, Glasgow), at 7.30.—C. H. Macmillan: Marine Motor Installation.

BRITISH ASSOCIATION OF CHEMISTS (Birmingham Section) (in Medical Theatre, Birmingham University), at 7.45.—Dr. F. W. Aston: Atomic Weights and Isotopes.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—D. S. McColl: Sculpture in relation to Architecture.

ARISTOTELIAN SOCIETY (at University of London Club), at 8.—Dr. J. Drever: The Meaning of Consciousness for the Psychologist.

ROYAL SOCIETY OF ARTS, at 8.—Dr. W. Rosenhain: The Inner Structure of Alloys (Cantor Lectures) (I.).

FARADAY SOCIETY (at Chemical Society), at 8.—Prof. A. J. Allmand and V. S. Puri: The Effect of Superposed Alternating Current on the Anodic Solution of Gold in Hydrochloric Acid.—Prof. C. H. Desch and

Eileen Vellan: The Electrolytic Deposition of Cadmium and other Metals on Aluminium.—W. M. Thornton and J. A. Harle: The Electrolytic Corrosion on Ferrous Metals.—S. Glasstone: Overvoltage and Surface Forces at the Lead Cathode.—M. Shikata: The Electrolysis of Nitrobenzene with the Mercury-dropping Cathode.—J. R. Coutts: The Law of Distribution of Particles in Colloidal Suspensions: A Note on the Specific Volume of a Gamboge Suspension.—W. W. Barkas: The Distribution of Particles in Colloidal Suspensions.

CAMBRIDGE PHILOSOPHICAL SOCIETY (in Botany School, Cambridge), at 8.45.—Prof. D. M. S. Watson: Orthogenesis.

MEDICAL SOCIETY OF LONDON, at 9.—Sir Bernard Spilsbury: Wounds and other Injuries (Lettsomian Lectures) (I.).

CHEMICAL INDUSTRY CLUB (at 2 Whitehall Court).

TUESDAY, FEBRUARY 17.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.15.—Prof. J. Barcroft: The Colour of the Animal Creation (II.). The Colour of the Hare.

ROYAL STATISTICAL SOCIETY (at Royal Society of Arts), at 5.15.—E. J. Russell and T. Ediser: The Fishery Statistics of England and Wales.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—Secretary: Report on the Additions made to the Society's Menagerie during the month of January 1925.—Major S. S. Flower: Contributions to our Knowledge of the Duration of Life in Vertebrate Animals.—I. Fishes, II. Batrachians.—R. I. Pocock: (*a*) The External Characters of an American Badger (*Taxidea taxus*) and an American Mink (*Mustela vison*) recently exhibited in the Society's Gardens; (*b*) Additional Notes on the External Characters of some Platyrhine Monkeys.—Dr. R. Broom: The Origin of Lizards.—A. Loveridge: *Natrix alliaceus* Peters (Reptilia), from Pemba Island, and other Notes.—E. P. Allis, jun.: The Origin of the V-shaped Branchial Arch in the Teleostomi.

INSTITUTION OF ELECTRICAL ENGINEERS (North Western Centre) (at Engineers Club, Manchester), at 7.—H. W. Clothier: The Design of Electrical Plant, Control Gear, and Connexions for Protection against Shock, Fire, and Faults.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (Kinematograph Group), at 7.—C. F. Elwell: The De Forest Phonofilms.

INSTITUTE OF CHEMISTRY AND SOCIETY OF CHEMICAL INDUSTRY (at 36 York Place, Edinburgh), at 7.30.—T. Bolam, W. O. Kermack, W. T. H. Williamson, and others: Discussion on The Stability of Colloids.

INSTITUTION OF ELECTRICAL ENGINEERS (Scottish Centre) (at Freemasons' Hall, Edinburgh), at 7.45.—Prof. G. W. O. Howe: World-wide Radio Telegraphy (Faraday Lecture).

HULL CHEMICAL AND ENGINEERING SOCIETY (at Grey Street, Hull), at 7.45.—R. A. Bellwood: The Romance of the Vegetable Oils.

WEDNESDAY, FEBRUARY 18.

SOCIETY OF GLASS TECHNOLOGY (at Sheffield), at 2.30.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Dr. G. Scott Williamson: The Anatomy and Physiology of the Thyroid Apparatus (I.).

SOCIETY OF CHEMICAL INDUSTRY (Liverpool Section) (jointly with the Liverpool Geological Society) (in Chemistry Department, Liverpool University), at 6.—Prof. P. G. H. Boswell: Mineral Oil: Supplies of the Present and Future.

INSTITUTION OF CIVIL ENGINEERS (Students' Meeting), at 6.—R. H. Tangri: Reconstruction of Barrow Haven Bridge, Lincolnshire, L. and N. E. Ry.

INSTITUTION OF ELECTRICAL ENGINEERS (South Midland Centre) (at Birmingham University), at 7.—H. W. Clothier: The Design of Electrical Plant, Control Gear, and Connexions for Protection against Shock, Fire, and Faults.

INSTITUTION OF AUTOMOBILE ENGINEERS (Birmingham Graduates' Meeting) (at Chamber of Commerce, Birmingham), at 7.30.

SOCIETY OF CHEMICAL INDUSTRY (Newcastle Section) (at Armstrong College), at 7.30.—Prof. H. V. A. Briscoe and P. L. Robinson: A Redetermination of the Atomic Weight of Boron.

INSTITUTION OF ELECTRICAL ENGINEERS (Sheffield Sub Centre) (at Royal Victoria Hotel, Sheffield), at 7.30.—W. B. Woodhouse: Presidential Address.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—Miss L. Doris Sawyer: The Effect of Pressure Distribution upon London's Sunshine in Winter.—Prof. S. Chapman: On the Changes of Temperature in the Lower Atmosphere, by Eddy Conduction and otherwise.—N. K. Johnson and C. F. T. Roberts: The Measurement of the Lapse Rate by an Optical Method.

ROYAL SOCIETY OF ARTS, at 8.—Dr. J. S. Owens: Modern Atmospheric Conditions.

IPSWICH AND DISTRICT NATURAL HISTORY SOCIETY.—J. M. Hill: Primitive Medicine and Folk-lore of the Guiana Indians.

THURSDAY, FEBRUARY 19.

MEDICO-PSYCHOLOGICAL ASSOCIATION (at Royal College of Physicians, Edinburgh), at 2.30.—Dr. D. Slight: The Psycho-galvanic Reaction.—Dr. G. Gibson: The Boarding out System.—Dr. W. M. McAlister: Results of Treatment of General Paralysis by Malaria.

ROYAL SOCIETY, at 4.30.—Prof. O. W. Richardson and A. F. A. Young: The Thermionic Work-Functions and Photoelectric Thresholds of the Alkali Metals.—J. H. Brinkworth: The Measurement of the Ratio of the Specific Heats using Small Volumes of Gas.—F. H. Constable: The Catalytic Action of Copper: Parts VI. and VII.—V. H. Stott, Edith Irvine, and D. Turner: Viscosity Measurements of Glass.—*To be read in title only*.—W. G. Palmer and F. H. Constable: The Catalytic Action of Copper: Part V.—P. A. M. Dirac: The Adiabatic Invariance of the Quantum Integrals.—D. L. Watson: The Thermal Decomposition of Derivatives of Oxalacetic Ester.—A. Unimolecular Reaction.—K. R. Rao: (1) The Fluorescence and Channelled Absorption of Bismuth at High Temperatures, (2) A Note on the Absorption of the Green Line of Thallium Vapour.

LINNEAN SOCIETY OF LONDON, at 5.—Miss A. Lorrain Smith: John Templeton's Drawings of Lichens and Fungi.—Dr. J. Burtt-Davy: The Tropical African Element in the Arborescent Flora of the Transvaal.—Prof. R. R. Gates: Virescent Inflorescence of Delphinium.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.15.—Sir William Bragg: The Properties and Structure of Quartz (IV.).

INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5.30.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—F. M. Alexander: An Unrecognised Principle in Human Behaviour.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—Major E. I. David: Electricity in Mines.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 7.—Lt.-Col. L. F. R. Fell: Light Aeroplane Engine Developments.

INSTITUTION OF ELECTRICAL ENGINEERS (Mersey and North Wales (Liverpool) Centre) (at Liverpool University), at 7.—W. E. Bush: Modern Electric Lighting Practice.

INSTITUTION OF AUTOMOBILE ENGINEERS (Derby Graduates' Meeting) (at Cavendish Café, Derby), at 7.30.—R. Bolton: The Early History of Road Transport.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, at 7.45.—Dr. H. Melenev: Demonstration on the Pathology of Experimental Leishmaniasis in the Hamster.—At 8.15.—Prof. B. Blacklock: Schistosomiasis and Goitre in Sierra Leone.

CHEMICAL SOCIETY, at 8.

SOCIETY OF DYERS AND COLOURISTS (West Riding Section).—Prof. E. C. C. Baly: Photosynthesis of Naturally Occurring Compounds.

FRIDAY, FEBRUARY 20.

GEOLOGICAL SOCIETY OF LONDON, at 8.—Annual General Meeting.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Dr. G. Scott Williamson: The Anatomy and Physiology of the Thyroid Apparatus (II.).

SOCIETY OF CHEMICAL INDUSTRY (Liverpool Section) (at Liverpool University), at 6.—Discussion.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Annual General Meeting.

INSTITUTION OF ELECTRICAL ENGINEERS (South Midland Centre) (at City Council Chamber, Birmingham), at 7.—W. B. Woodhouse: Presidential Address.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (Pictorial Group), at 7.—A. C. Banfield: Photography by Artificial Light.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—J. N. Seddon: Inverted Tooth Chain Drives.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. T. H. Pear: Acquiring Muscular Skill.

SOCIETY OF DYERS AND COLOURISTS (Manchester Section) (at 36 George Street, Manchester).—D. A. Gibbens: Some Work done in the Chemical Department of the Shirley Institute.

INSTITUTION OF ENGINEERING INSPECTORS.—Major C. E. S. Phillips: The Radium Industry.

SATURDAY, FEBRUARY 21.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—W. Rothenstein: The Artist's Relation to Social and Religious Life (II.).

PHYSIOLOGICAL SOCIETY (at London School of Medicine for Women).

PUBLIC LECTURES.

SATURDAY, FEBRUARY 14.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—R. Lovett: Natural History in Folk-lore.

MONDAY, FEBRUARY 16.

ST. BARTHOLOMEW'S HOSPITAL MEDICAL COLLEGE, at 5.—Sir William I. de Courcy Wheeler: Some Practical Considerations and Experiences in the Conservative Treatment of Fractures of the Pelvis and the Lower Extremity (I.). (Succeeding Lectures on February 17, 18, 19.)

LONDON SCHOOL OF ECONOMICS AND POLITICAL SCIENCE, at 5.—Dr. E. B. Behrens: Organising an International Civil Service for Purposes of Industrial Research.

UNIVERSITY OF LEEDS, at 5.15.—Dr. H. H. Dale: Anaphylaxis.

MEDICAL SOCIETY OF LONDON, at 5.15.—Prof. E. W. Hope: International Hygiene (Chadwick Lecture).

BIRKBECK COLLEGE, at 5.30.—Dr. G. G. Coulton: Medieval Education (III.). Spoken Latin in the Middle Ages.

KING'S COLLEGE, at 5.30.—Prof. A. E. Jolliffe: English Mathematics before Newton.

TUESDAY, FEBRUARY 17.

KING'S COLLEGE, at 5.30.—Miss Evelyn Underhill: The Realism of the Mystics.

UNIVERSITY COLLEGE, at 5.30.—Prof. J. E. G. de Montmorency: The Significance of the Humanism of the Negro Races.

GRESHAM COLLEGE, at 6.—Sir H. Walford Davies: Music. (Succeeding Lectures on February 18, 19, 20.)

UNIVERSITY OF LEEDS, at 8.—Prof. J. H. Priestley: Moorland Plants.

WEDNESDAY, FEBRUARY 18.

LONDON SCHOOL OF ECONOMICS AND POLITICAL SCIENCE, at 5.—J. Thorp: The Principles of Design as applied to Books and Printing.

KING'S COLLEGE, at 5.30.—Baron A. F. Meyendorff: Travels in the East. A.D. 800–1200.

UNIVERSITY COLLEGE, at 5.30.—A. Gomme: Technical and Scientific Libraries.

THURSDAY, FEBRUARY 19.

KING'S COLLEGE, at 5.30.—Dr. I. P. Bruce: Education in China.

CENTRAL LIBRARY, 598 Fulham Road, at 8.—A. J. Linford: England's Story in Stone.

SATURDAY, FEBRUARY 21.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—F. Balfour Browne: My Journey to Brazil.

SATURDAY, FEBRUARY 21, 1925.

Words, Meanings, and Styles.

I.

FOR several weeks various opinions have been expressed in our correspondence columns as to the desirability or otherwise of using the word scientist to designate in a generic sense any one actively engaged in the advancement of natural knowledge by investigation. The term is not an Americanism, as is often supposed, but was introduced by Dr. Whewell in 1840 "to describe a cultivator of science in general." In a letter published in NATURE of November 29, Dr. Norman Campbell pleaded for approval of the word, and asked objectors to suggest a single substitute for it if they were not willing to adopt it. We invited opinions upon the question from a number of distinguished representatives of letters as well as of science, and have published some of the replies with which they have favoured us. The general attitude of scientific workers was clearly stated by Sir Ray Lankester in our issue of December 6; and it is one of dislike. Literary authorities, on the other hand, are prepared to give the word a legitimate place in the English language, and they point to many similar hybrids which have been admitted into our vocabulary without question.

It cannot be said that, as the result of the discussion, any single word has been suggested which is likely to come into general use as a substitute for scientist. Some of our correspondents have expressed complete abhorrence of this term, others have given unwilling acceptance to it, and a third group approves of it. While, therefore, we do not propose to depart from our custom of avoiding the word in our own practice, or in unsigned contributions for which we accept editorial responsibility, we are content to leave individual authors to use it or not, as they may prefer. Our opinion is that one of the main objections to the word is that it is too comprehensive in its meaning. Sir Israel Gollancz thinks the word should not be limited to workers in the field of physical or biological science, and Prof. Wildon Carr would make it imply philosophers as well as such workers. What they apparently desire is a word which is equivalent to the French savant or the German Gelehrte, but it can scarcely be said that the term scientist was coined with this intention.

The fact is that, in these days of specialised scientific investigation, no one presumes to be "a cultivator of science in general." A man is a chemist, physicist, biologist, botanist, or worker in one or more particular branches of science, and he prefers to be designated as such rather than to be placed in an indefinite group of "scientists." In an artificial language like Esperanto, it is easy to assign a single termination, such as "ist," to all professional occupations, but no hard and fast rule of this kind can be imposed upon the structure

of a living language. Certain words come into use, while others are discarded, and no purely logical or etymological plan of formation is practicable. "Mathist" and "electrist" may, as Sir Richard Paget suggests, be improvements upon "mathematician" and "electrician," and Prof Armstrong's "sciencer" may be a suitable substitute for the word "scientist," but whether the termination be "ist" or "er," custom alone will decide which will survive. We have geographer and geologist, engineer and technologist, philosopher and physicist, astronomer and spectroscopist, all in common use, whether rightly or wrongly formed. The public has similarly accepted "scientist" to signify a follower of science of any kind, and will continue to use it even though it is not approved as good currency in the scientific world.

An inquiry of the secretaries of the leading British scientific societies shows that the word is very rarely used in their publications and is always avoided when it can be conveniently avoided It is not used officially by the Royal Society of London or of Edinburgh, the British Association, or the Royal Institution, and each of these bodies often has occasion to refer to workers in science as a whole. The feeling of the Cambridge University Press is strongly against the use of the word scientist, and when, in one instance, it occurred in the title of a work submitted to the Syndics, a strong protest was raised and the title of the book was altered On the other hand, the Clarendon Press, Oxford, does not object to the word being used in its books, and says: "Of course we avoid any attempt to legislate and are guided principally by usage." There is no doubt whatever that the balance of feeling in scientific circles is against the word. Whatever its future, therefore, we are not prepared to depart from our practice hitherto of avoiding the word, and we leave it to others to convert it into the currency of cultured usage.

The variety of opinion on the recognition of the word scientist enables a conception to be formed of the labour involved in providing a good technical vocabulary for a new subject such as aeronautics. There is, first of all, the difficulty of setting up a systematic nomenclature with reasonable claims to be logical without being pedantic. In addition, there is the still greater difficulty of obtaining general acceptance by such diverse people as mathematical physicists, technical engineers, constructors, pilots, mechanics, the Services, and last, adoption by the press, most influential of all. The Technical Terms Committee of the Royal Aeronautical Society, which was reconstituted in 1920 as a section of the British Engineering Standards Association, produced the present officially accepted glossary for aeronautics; and the Advisory Committee for Aeronautics in the U.S.A. has shown much broad-mindedness in adopting the great majority of the British findings. There are important exceptions, however. Dr. Alexander McAdie, director of the Harvard meteorological station at Blue Hill, in writing to us about the word scientist comments on the continued use of the form "aeroplane" in Great Britain, replaced by "airplane" in America.

Generally speaking, it will be found that, in the official glossary for aeronautics, *air-* is compounded with common English words, or with words derived through the French language, while *aero-* is compounded with technical terms of direct Latin or Greek origin. Thus: *Air- man, ship, craft, shed, screw*, but *aero- stat, naut, bate, dynamics*, etc. *Aerofoil* is an exception and should be either *airfoil* or *aerofolium* *Aeroplane* is right by the rule, but *seaplane*, introduced by the Admiralty during Mr. Churchill's regime, and *landplane, floatplane, wheelplane* proposed but not yet accepted, all justify *airplane* *Airplain* is ruled out by the lack of association of *plain* with wing-like structures; but the influence of the French word *aéroplane*, the interest vested in the title of our own liveliest of technical periodicals, and ingrained use, will prevent the giving up of the form *aeroplane* for a long time. A very stout battle has been fought over the introduction of *air-screw* to avoid such combinations as *tractor propeller* and *pusher propeller* which are retained in the U.S.A. vocabulary. The most awkward gap in the language of aeronautics is due to the want of words to denote aircraft both lighter than air and heavier than air. *Aerodyne* was proposed by analogy with *aerostat*, but nothing more has been heard of it, *H/A craft* and *L/A craft* beg the question, and it may be hoped that *lighter-than-air-craft* will not survive. In the face of these few examples of the difficulties which crop up in a technical vocabulary, it is a bold prophet who will predict the terms around which the language will finally crystallise.

In discussing the use or disuse in English of any particular word, the very mixed origin of our language must, of course, be borne in mind. Anglo-Saxon, Latin and Greek have all provided roots which appear in words in general use, while, if the vocabularies of the sciences and arts are taken into consideration, it is clear that a much wider range of languages has also been used. This may perhaps account for the ease with which foreign words are introduced, often as slang at first, and eventually adopted, with little if any change in spelling. It should also incline us to be tolerant of hybrid words, though, of course, the making of new hybrids, unlike the work of the plant-breeder, cannot be expected to be productive of beauty and increased usefulness, and should be discouraged.

The question is discussed in an interesting article

by Mr. George H. Bonner in the December issue of the *Nineteenth Century*. The real point is this: A word having crept into use, what is to be the ultimate authority for discarding or retaining that word as a definite part of the English language? In France the decision is in the hands of the Academy. A word is "adopted" or otherwise and the writers of the day follow, more or less, the recommendations made. But that will not prevent the use of a word in conversation and by the general public. After all, it is the growth of popularity of a word which is a factor in bringing it to the notice of the Academy. If a new word is useful in that it conveys an exact meaning not readily expressed in a word or concise phrase at present accepted as legitimate, it would seem that popular usage will gradually enforce its adoption. Thus the vocabulary of a language, if it is to meet the demands made upon it by a progressive people, must be continuously in a state of flux.

This may explain, in part, why so little progress has been made in the adoption of an international language Apart from the claims of nationalism, which have been increasingly insistent during the past few years, "living" languages must, with the growth of new ideas and the introduction of foreign elements, be always developing. It therefore becomes difficult for those who are not, as it were, "living with the language," to keep pace with changes of meaning. As regard purely artificial languages, the question of following the dictates of an academic central authority again arises. The authority, in most cases, will trail behind popular usage.

There is, however, a further consideration, as Mr. Bonner points out in the article to which we have referred. The language of conversation is not normally the language of serious writing In talking, the periods are generally comparatively short and the argument often gains by the use of terse and incisive expressions which would be totally out of place in written contributions. When it is a question of placing on record, for serious discussion and reflection, facts and thoughts which represent additions to the sum of human knowledge, then accuracy of meaning and dignity of expression should be the rule. Here again, in English, popular usage would seem to be the ultimate authority, though with the restriction that "popular usage" should refer to the diction and style of the better educated and more intellectual of the community. The language of a progressive people must itself be progressive; and as the word scientist expresses more clearly and with less ambiguity than any other single word the meaning it is intended to convey, it is likely to survive the dislike which scientific workers in general have for it.

Continental Drift.

The Origin of Continents and Oceans By Prof. Alfred Wegener. Translated from the third German edition by J G A. Skerl. Pp. xx + 212 (London: Methuen and Co., Ltd., 1924.) 10*s* 6*d*. net.

THE wide appeal of Prof. Wegener's theory of the arrangement of ocean and continent is shown by the issue of a third greatly revised edition and of this excellent English translation. His theory is that the continents consist of rigid blocks of sial, or rock characterised by a high percentage of silica and alumina, which are floating partly submerged in a sheet of sima, or rock material composed mainly of silica and magnesia; that the existing continents are due to the breaking up of a once continuous sheet of sial, the fragments of which have drifted to their present positions in consequence of the earth's rotation; and that this drift occurs owing to the plasticity of the sima Prof. Wegener believes that the continents have been moved for great distances even in geologically recent times, and he thereby, with great ingenuity and attractiveness, explains many problems of geography, geology, climatology, biology, and geodetics The process offers an easy escape from difficulties and is not to be dismissed as impossible or scouted as fantastic, for in all probability sima is more plastic than sial, and the rotation of the world must make the continental masses tend to lag westward, and press centrifugally toward the equator The view that the continental masses are subject to some horizontal drift has been often adopted, as, for example, by the reviewer in 1915 (*Scot. Geog. Mag.*, 31, pp. 258-60) to explain the folded nature of the Pacific margin of America, in contrast to the coastal structure on both sides of the Atlantic, and the prevalence of fiords on western coasts. There is no *a priori* objection to the principle, and the verdict on Prof. Wegener's theory will depend on whether it explains more difficulties than it creates.

The author's interesting discussion of the geophysical arguments shows that on this branch of the subject the primary facts are still uncertain In spite of the apparent precision of mathematical methods, the data are so inexact that the results are inconclusive. Prof. Wegener's theory will, however, probably give a new lease of life to the explanation of the Carboniferous glaciation of India and of some parts of the Southern Hemisphere, by the shifting of the Pole; for arguments, which are unanswerable against that explanation with scattered continents, do not apply to Prof. Wegener's single continent.

The theory of continental drift was suggested by that coincidence in course of the opposite coasts of the

Atlantic, which is one of the best known of the geographical homologies. Its significance was remarked by Bacon. Prof. Wegener has the advantage over Lord Bacon that the geological evidence now supports the inferences from geographical shape; for the opposite parts of the Atlantic show remarkable resemblances in structure and composition. The agreements, according to Wegener, are due to the coasts having been originally in contact, and having been separated by a curved fracture which was widened into the Atlantic basin, owing to the land west of the rift having drifted away as America. The agreement in grain of the lands on the two sides of the Atlantic is, however, also capable of explanation by vertical movements of the crust If two pieces of wood with the grain of each in line are seen in a sheet of water, it does not follow that they were originally in contact and have floated apart. They may be the ends of a warped plank, of which the middle has sunk beneath the surface. The Appalachian and Armorican Mountains may have belonged to a continuous mountain belt without their having been actually adjacent, just as the Pyrenees and the Caucasus are regarded as part of one mountain system although they have always been separated by the full width of Europe. In fact, the differences between the Appalachians and the corresponding mountains in Western Europe indicate that they were probably formed some distance apart The problem is whether the corresponding structures on opposite sides of the Atlantic have been separated by a two-mile subsidence of the intervening area, or by the horizontal drift of America for 2000 or 3000 miles.

Individual judgments on this question depend upon the theory accepted of the structure of the earth; and long before any agreement is reached by this route, the displacement theory should be proved or dismissed by direct observation According to Prof. Wegener, southern Greenland is moving away from Scotland at the rate of from 18 to 36 metres a year, and Iceland is drifting away from Norway from 18 to 19 metres a year. The estimate for Greenland rests on the difference of longitudes determined by the *Germania* expedition of 1870 and the Danish expedition of 1907; they were determined by lunars and are not convincing. Wireless determinations of longitude at intervals of five or ten years should soon provide an absolute test of the theory, as is remarked by Dr. Evans in his interesting introduction to the volume.

The movement in the central Atlantic is regarded as slower than in the north, yet as increasing the distance between Brazil and the Cameroons eight inches a year. The growth of the tropical Atlantic, according to Prof. Wegener's table, has taken about 20 million years, though at the rate of drift assigned to Brazil, the time should have been 40 million years; therefore, according to the geological dates accepted on p. 113, the formation of the tropical Atlantic began in the early Mesozoic. The westward drift of South America is regarded as a long-continued process, and its crumpling effect on South America should have been widespread and continuous. The folding of the Andean belt was intermittent and happened at distant dates; but the folding that made the existing Andes happened in a relatively short period. That condition is consistent with the explanation of the Andean folding by a western lag which has been previously referred to, as the lag was attributed to instability due to vertical movements in the crust at one geological period; but without some acceleration of the westward movement in the middle Kainozoic, Wegener's continental drift does not explain the formation of the western fold mountains of America. Moreover, as the author shows in the fifth chapter from the palæontological evidence, the land connexion across the Atlantic was established and broken several times; so the displacement theory requires a concertina-like movement, America being pushed first west and then east. A vertical oscillation of the crust presents no difficulty comparable to that of an oscillatory horizontal passage of the Americas to and fro across the Atlantic.

A horizontal oscillation of even that amount is, however, insufficient. The displacement hypothesis is advocated from biogeography on, amongst other grounds, the occurrence on both sides of the Atlantic of animals and plants which apparently crossed it in about their present latitudes, and that shallow water marine animals, to which the deep seas are almost as impassable as to land animals, show the former range of shallow water along the same zones. The argument based on the marine animals appeals to the reviewer as one of his earliest papers urged it from the evidence of the fossil Echinoidea. Prof. Wegener quotes the manatee, which lives in the estuaries of West Africa and South America and is not likely to have crossed an ocean so wide as the Atlantic There is, however, similar evidence of land connexion across the Pacific. The alligator is now found only in the Yangtze Kiang in China, and in the warmer parts of America; and it is no more likely to have crossed the open ocean or rounded the Pacific by Bering Straits than the manatee is to have crossed the Atlantic via Iceland and Greenland. Some lizards, amphibians, and the main flora of China support the evidence of the alligator as to a former land route across the Pacific to America. It is, however, essential to Prof. Wegener's case that Western America and the eastern lands of the Old World should have been previously farther apart than they are to-day; for before the separation of the Americas from Europe

and Africa the Pacific must have been wider. Prof. Wegener remarks (p. 86) that some of the earthworms of Australasia and New Zealand not only reach India but also, "strange to say, occasionally the west coast of North America."

This range of Australasian worms to western America is one item in a mass of biological evidence inconsistent with the view that America has been drifting westward into the Pacific. For example, Pritchardia, the characteristic palm of the south-western Pacific, is known elsewhere only in the Sandwich Islands and in Cuba, where its unexpected occurrence was attributed by Beccari to its fruits having been hurled from Polynesia by a volcanic eruption. According to Dr. Scharff, one element in the flora of the islands off western Mexico represents the eastern range of a central Pacific flora which was partly of Australasian and Eastern origin. Similarly, according to Pilsbury, the distribution of the land shells demands radial migration from a central Pacific land. Its existence is also indicated by the coral islands and by the contours of the Pacific floor.

The existence of a land connexion from America westward across the Pacific is, however, wholly inconsistent with the present form of the displacement theory. If the pilgrims had been rafted across the Pacific on migrating lands, America, after its separation from the western side of the Old World, not only drifted westward until it bumped against eastern Asia, but also has floated back to its present position. Unluckily for this explanation, the trans-Pacific and trans-Atlantic connexions are required at about the same time. Hence it would be necessary to assume that the sial mass of America at one time lost its rigidity and, like a rubber bladder, spread out as a thin sheet over both the Atlantic and Pacific basins; and that afterwards it contracted and thickened to form a meridional bolster. The original theory has undergone so many modifications, and its author is so delightfully open-minded, that it may be changed to agree with a trans-Pacific land connexion. The theory at present is inconsistent with so many facts that Prof. Wegener's calculation, that the odds based on the grain of the Atlantic shores are a million to one in his favour (p. 56), do not hold for the whole of his case.

The favourable reception of Prof. Wegener's theory is significant of marked changes of opinion as regards the structure and history of the earth. It shows that the once widely adopted view that oceans and continents have always been in their present positions no longer hampers geological interpretation, and it marks the growing belief in the effective mobility of the earth's crust.

J. W. GREGORY.

Greek Alchemy.

Union Académique Internationale. Catalogue des manuscrits alchimiques grecs. 1: Les *Parisini*. Décrits par Henri Lebègue. En Appendice, Les manuscrits des *Coeranides* et tables générales, par Marie Delcourt. Pp. x+320. n.p. 3: Les manuscrits des Îles Britanniques. Décrits par Dorothea Waley Singer, avec la collaboration d'Annie Anderson et William J. Anderson En appendice, Les recettes alchimiques de *Codex Holkhamicus*, éditées par Otto Lagercrantz. Pp. vii+84. n p. (Bruxelles: Maurice Lamertin, 1924.)

NO one who has not himself rummaged among the old chemical manuscripts in the great libraries can have any idea of the vast quantity of material which awaits investigation. Even the printed literature of the fifteenth to seventeenth centuries has been by no means fully studied, but of the earlier manuscript material only a fraction has hitherto been examined. This neglect is reflected in our histories of chemistry, which commonly begin seriously with Priestley and Lavoisier, by whose time chemistry was already well established on lines not widely different from those of to-day. The earlier periods are usually dealt with very summarily, since to give an adequate account of them, in the present state of our knowledge, would entail years of laborious work upon the original sources. The very ideas themselves, from their unfamiliar nature, often seem entirely unintelligible.

Any contributions, however small, to the accomplishment of the task presented to us by this unstudied material would therefore be certain of a warm welcome. When, however, they are of the standard and magnitude of the "Catalogue des manuscrits alchimiques grecs," it becomes difficult to express our thanks adequately. For our knowledge of Greek alchemy we have had to rely practically entirely upon the work of Berthelot and his collaborator Ruelle, whose "Collection des anciens alchimistes grecs" (3 vols., Paris, 1888) has been almost the sole source of our information on this subject. The recent revival of interest in the history of science has rendered it desirable to extend and amplify our knowledge of early chemistry, and it was very necessary to make a systematic investigation of all the extant manuscripts. Bibliographical research of this nature confers an inestimable boon upon later workers in the field, for it shows them at once what is and what is not available, and saves them more time than can readily be appreciated except by one who has suffered from the lack of such information.

That the present work is published under the direction of Profs. Bidez, Cumont, Heiberg, and Lagercrantz,

is a sufficient indication of its comprehensiveness and trustworthiness, two qualities which in an undertaking of this kind are absolutely indispensable. Unless one can be perfectly certain that a bibliography is full and accurate, one always has the uneasy feeling that something of importance may have been overlooked, and there is nothing more depressing.

Parts 1 and 3 of the Catalogue—all that are published so far—deal respectively with the Greek alchemical manuscripts in Paris and those of the British Isles. The first part, which is the work of M. Henri Lebègue, includes also a description of the MSS of the Koeranides by Mdlle M. Delcourt, who provides, in addition, comprehensive indices to the whole volume On the Koeranides or Kiranides—a work on the virtues of plants and animals—reference may be made to Thorndike's "History of Magic and Experimental Science," 1923, ii. ch. xlvi., and to Ruelle's "Lapidaires grecs," Paris, 1898. The Greek alchemical manuscripts at Paris are 19 in number. They are carefully described folio by folio, in such a way that a good idea is given of the whole contents When they have been edited, references are given to the edition Scholars, therefore, who desire information on the MSS. will find, ready to hand, all that is necessary to enable them to form a judgment

The third part, which deals with the manuscripts of the British Isles, is on similar lines It includes also two papyri, one at the British Museum (Papyrus 121) and one in the Bodleian [MS. Gr. f. 73 (p) 3396]; a manuscript of the Koeranides; and the text of the Byzantine Greek manuscript on alchemy (290, ff 186-194) preserved in the library of the Earl of Leicester at Holkham Hall. The last section is the work of Prof Otto Lagercrantz, the main portion of Part 3 was compiled by Mrs. Singer, with the collaboration of Miss Annie Anderson and Mr. W. J Anderson Mrs Singer's catalogue of the scientific manuscripts of the British Isles now includes about 40,000 items, and the present catalogue is the development of one of the sections of the general catalogue. Those who have had the privilege of using the latter—a courtesy which Mrs. Singer extends with unfailing generosity to all scholars—fully realise the tremendous assistance it will give to historical research in science, and will rejoice that this part of it is now in print.

The general impression gained from a perusal of the two parts is one of astonishment at the comprehensiveness of Berthelot and Ruelle's work. As M. Bidez says, "If the faults of Ruelle's work have become apparent, it is the result of a new scientific curiosity which he was one of the first to awaken." We cannot doubt that the publication of the present Catalogue will stimulate research into the origin of chemistry; it will certainly render the task of workers in this field very much easier. It is, moreover, not without interest to Hellenists themselves, for surely no student of Greece can afford to neglect this early scientific or quasi-scientific literature.

The important Holkham Hall manuscript, which, at Sir Frederick Kenyon's request, the Earl of Leicester kindly allowed to be published, was brought to light by Prof. Cumont It has here been edited, with an introduction and critical annotations, by Prof. Lagercrantz It is entitled "τῆς ἀλτεμίας ἡ διαταξις καὶ ἡ συμβολὲς καὶ ἡ κόπρωι—alchimiae apparatio et compositiones et fimi"—and is interesting not only because of the strange substitution of ἀλτεμία for ἀλχημία or ἀλχυμία (a point which Prof. Lagercrantz discusses in his preface), but also because it shows that the Byzantines had original views on alchemy and did not confine themselves to reading and interpreting the works of the ancient Greek alchemists. We hope that it may prove possible to publish a translation of this MS into English, French, or German, and so to make it more easily accessible.

E. J. HOLMYARD

Our Bookshelf.

Introduction to the Theory of Spectacles. By Prof. Dr. Otto Henker Translated by R Kanthack. Pp. viii+336. (Jena: School of Optics; London: J W Atha and Co., 1924.) 13*s.* 6*d.*

THE book under notice follows the lines of Prof. Henker's courses of lectures on spectacles; the German edition from which the present translation by Mr Kanthack is made was first published in 1921. Commencing from elementary principles, it gives an account of modern continental practice in spectacle optics, embodying the important work (in connexion with cataract lenses, telescopic spectacles, and other special aids to vision) of the Jena school under Prof. Moritz von Rohr. This has been mainly accomplished since the year 1908 While the War with its immense number of special cases of injuries to the eye undoubtedly gave a renewed stimulus to studies of this kind, many sufferers are still (as Prof. Cheshire points out in a foreword) ignorant of the aid which science can now give them. The present book should fill a great need if it gives information of this kind.

The mathematical theory goes no further than the usual Gaussian first-order treatment, but aberrational defects and means of overcoming them are explained with the aid of diagrams. The analogy between the action of the anastigmatic spectacle lens (with its stop at the centre of rotation of the eyeball) and the single photographic landscape lens, in securing freedom from the astigmatism of oblique pencils, emphasises the fact, not yet sufficiently appreciated, that a spectacle lens must be designed with the same understanding and similarly thorough analytical and trigonometric methods as for any other optical instrument. As

Gullstrand pointed out, such anastigmatism cannot be secured in high-power cataract lenses without the use of non-spherical surfaces. The design of such lenses by Prof. von Rohr and their production by Zeiss is one of the most interesting matters dealt with in the book. The importance of this work to ophthalmological science cannot be too fully emphasised.

A number of terms and phrases are found which should not be adopted in Great Britain without question. There are good reasons against the term "point-focal" as applied to any lens whatever, and there is no need to replace the familiar term "bending" (as applied to a lens) by "co-flexure." Other examples will be found

The number of tables and charts which the book contains render it in fact a very useful work of reference for the ophthalmologist, though it is undoubtedly more than an "introduction to the theory of spectacles"; its scientific importance is unquestionable.

The British Journal Photographic Almanac and Photographer's Daily Companion; with which is incorporated "The Year Book of Photography and Amateurs' Guide" and "The Photographic Annual," 1925 Edited by George E Brown Sixty-fourth issue. Pp 816. (London: H. Greenwood and Co., Ltd, 1925) Paper, 2s net; cloth, 3s net.

THIS almanac continues to occupy the unique position that its editor has earned for it, and to have lived down all its previous contemporaries. Its general character is too well known to need description, and is maintained in the present volume, but a few welcome changes have been introduced. The most notable of these is the replacement of the tables of chemical formulæ by a series of short articles dealing with the properties of the commonest of the chemical substances used in photographic processes. These will be found of real practical utility, though they need a little revision One might, for example, be led into error by the statement that iodine is insoluble in water or by the representation of oxalic acid as if its crystals were anhydrous. There does not seem any valid reason for calling ammonium, potassium, and sodium salts as ammonium, "potass," and soda salts respectively, and when uniformity means simplicity and offers no disadvantages, it is always desirable. The editor as usual contributes a long article, this year on "The Plain Facts of Lenses," which is eminently practical and easily understandable even by non-technical photographers. There is also a second article by Mr. T. L. J. Bentley on how to get the best results with the very small cameras that are now in vogue. It appears that 3¼ in. × 2¼ in. is by far the most popular size as compared with either larger or smaller sizes of spools of roll-film.

Life and Science. By Prof. David Fraser Harris. Pp. 204. (London: Andrew Melrose, Ltd., 1923.) 7s. 6d. net.

THE author, in this little work, describes in simple terms the scientific aspect of certain vital phenomena. Written in pleasant style, it appears suitable for the layman of an inquiring turn of mind, who wishes to know something of vital mechanisms without the need of a knowledge of physiology. The work opens with a chapter on the thesis that there is nothing new under the sun, and shows how man's inventions have been anticipated in the mechanisms found in his own body. After a chapter on mechanisms of defence, the author describes certain tissues which are characterised by possessing a rhythmic activity, thus leading up to a discussion of sleep, which is termed "life's great rhythm". stress is laid on the presence of fatigue products in the blood, a lessened blood supply to the brain, and a diminution in the number of sensory impressions reaching that organ In the following chapter examples of "latent life," taken from both the vegetable and animal kingdoms, are described in the next, the rather uncommon subject of "coloured thinking" is dealt with; in these persons certain words or sounds are associated with certain colours, especially when a concept has to be visualised. the condition occurs in perfectly normal people and has no relation to visual hallucinations. The book closes with a plea for a greater recognition of the mutual influence of the mind and body upon each other, illustrated by the subject of faith-healing.

Sunshine and Open Air. their Influence on Health, with special reference to the Alpine Climate By Leonard Hill Pp. vii + 132 + 8 plates (London E. Arnold and Co, 1924) 10s. 6d. net

PROF. LEONARD HILL has brought together in small compass a mass of valuable material bearing on the health-giving properties of sunshine and open air. He analyses the scientific facts which explain the curative effects of the Alpine climate, contrasting the composition and physiological effects of high and low atmospheres. The value of this section is enhanced by a large series of comparative observations, not only on the hours of bright sunshine in numerous stations, but also by the exact measurement of the intensity of the sunlight and that of light reflected from the sky and the ground. These measurements are made both in terms of heat and of their biological action. The chapter on the influence of moisture, mist, temperature is well worthy of careful consideration, as it offers explanations of the morbidity of the town dweller and the risks of infection run in confined sunless communities In the chapter on the biological action of light, the author has summarised a large amount of valuable work done under his supervision in the Department of Applied Physiology in the National Institute for Medical Research. This work comprises the development of instruments for the precise measurement of actinic light both chemically and by its action on protozoa, the depth of penetration of various radiations, and their influence on the blood of animals and man The introductory chapter gives a practical account of the writer's personal experiences of the "sun cure," and the work is illustrated by some very clear half-tone reproductions.

The Chemistry of Crop Production. By Prof T. B. Wood. Second edition. Pp. vii + 193. (London: University Tutorial Press, Ltd., 1924.) 4s. 6d.

THE first edition of Prof. T. B. Wood's admirable little book on the scientific principles of crop production was reviewed in NATURE for March 24, 1921 (vol. 107, p. 101). We are glad to note that a second edition has been called for, and that the publishers have found it possible to reduce the price from 5s. 6d. to 4s. 6d. The text is unchanged, save that the examples are now based on prices current in 1924.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Solar Eclipse of January 24 and Wireless Signals.

DURING the solar eclipse of Saturday, January 24, the engineers of the Post Office and of the International Western Electric Company, at the instance of Admiral Sir Henry Jackson, measured the strength of wireless signals received from New York at Chedzoy in Somerset and at New Southgate, London. The results show that the signal strength rose to a sharp maximum and fell to a very sharp minimum during the progress of the eclipse.

At 14.12 G.M.T. totality occurred at New York and more than half of the trans-Atlantic track of the signals was in partial darkness; at this instant the strength of the signals received in England was observed to be about twenty per cent. above normal. At 14.52 first contact was visible in London, and by this time signals had increased to about double the normal strength. A few minutes later the centre of the total phase was in mid-Atlantic about 400 miles to the south of the wave track, and the whole of the track was now in partial darkness. The signal strength rose to a maximum first at Chedzoy and then at New Southgate. During the next half-hour the centre approached the wave track rapidly by moving in a north-easterly direction, and signal strength decreased greatly. At 15 30 the last contact occurred at New York, and at about 15 40 the signals received at both places of observation had fallen in strength to a minimum value less than one-fifth of the normal. At this instant about 300 miles of the western end of the wave track was in full daylight and the centre of the eclipse was crossing the wave track about 500 miles to the west of Ireland. By 15.45 the centre had moved beyond the Faroe Islands, daylight had returned, and at about 16 10 normal signal strength was regained. Throughout the eclipse directional measurements were made by the staff of the Radio Research Board, but no effect on bearings could be detected.

The occurrence of the maximum and minimum signal strengths on this occasion recalls the observations on the eclipse of Wednesday, April 17, 1912 (see NATURE, April 25, 1912, Vol. 89, p. 191). On that occasion, as there was no conveniently placed wireless station at work, the observations were made on "atmospherics" or "strays," which the meteorological conditions indicated were coming from Spain or North-west Africa. These earlier observations and also the new ones seem to be explained by the ionisation of the atmosphere by sunlight and the re-combination of the ions when the light is removed. This explanation was set forth in a paper read to the British Association in September 1912, as follows:—"My observations indicated that, firstly, when the penumbra stole over Western Europe and Western Africa propagation grew rapidly better; secondly, as the umbra itself crossed the Bay of Biscay towards France it began to hinder propagation, its interference being greatest after it had entered France near Les Sables, which means that at this moment it lay directly between London and the source of the strays; thirdly, that when the umbra passed on, the ionic medley it had created by re-combination of ions faded quickly" and propagation improved. The suggestion here is that the hurried and irregular re-combination of ions produced an ionic turmoil which obstructed electric waves. The obstruction arose, I suggested, not so much from absorption as from irregular refraction, the refraction being a consequence of the dependence of the velocity of electric waves through rarefied air upon the nature and concentration of the ions in it.

The interesting question now arises. What levels of the atmosphere are mainly concerned in these phenomena? Students of wireless telegraphy have long believed that there is an upper region in which free electrons exist more or less permanently and a middle atmosphere in which ions of molecular size are formed daily by sunlight. If I may quote again from my own writings: "Wireless investigators would suggest that the layer beneath the auroral layer is occupied by electrons that have come as beta-rays from the sun. The atmospheric pressure at above 50 kilometres is only about a millionth of an atmosphere, the mean free path of the electrons is therefore long and they may possibly remain permanently free in large numbers. It would seem that the base of this region charged with free electrons must be regarded as the ceiling usually known as the Heaviside layer." At night this ceiling reflects wireless waves of all lengths round the globe as a whispering gallery reflects sound. In the day the air below it is ionised, absorbs the waves in some degree, and gives to the rays a curvature which is greater as wave-length increases. To the Heaviside layer is attributed the "night effect" which afflicts direction finding. As no such effect was observed during the eclipse we may provisionally assume that the Heaviside layer did not come prominently into operation and that the middle heights of the atmosphere were responsible for the phenomena observed.

Sir Arthur Schuster, in his theory of the diurnal magnetic variations (Phil. Trans., A, 208, 1907, p. 182), requires that a portion of the upper atmosphere should possess a conductivity of 10^{-13} electromagnetic units in order to account for the usual variations. Prof. S. Chapman has of recent years elaborated this suggestion. But whether this portion of the atmosphere is above or below the Heaviside layer is not yet clear. It would seem that simultaneous observations of the effects of solar eclipses on the magnetic elements and on the propagation of signalling waves offers a means of solving this question.

Polarisation of Light from the Sky during the Solar Eclipse of January 24.

DURING the total eclipse on January 24, I was at New Haven, Connecticut, and thus very close to the middle line of the track of totality. For a portion of the period of totality I made a somewhat hasty survey of the state of polarisation of the light scattered by the sky, using for the purpose a Savart plate and Nicol prism. I was only able to cover the eastern sky from the zenith to the horizon stretching from north through east to south, and I was unfortunately not able to determine the plane of polarisation of the light scattered from the various parts of the sky. What I was able to note, however, with certainty was that there was no marked variation in the percentage of polarisation as one explored the eastward half of the sky—that is, there was no trace of the familiar maximum noted when the sun is not in eclipse.

As I am a physicist and not an astronomer I am not sufficiently familiar with the results of observations

of this sort at the time of previous eclipses to draw any conclusions from the fact I happened to note. It may be worth recording, however, as the conditions at the time of the eclipse of January 24 were somewhat unusual in that the entire country surrounding the path of totality was deeply covered with newly fallen snow, and it seems possible that a very large percentage of the diffused sky light may have come by previous scattering from the extensive snow fields on either side of the track of totality, and relatively very little from either the corona or the direct light from the sun on the edge of totality.

AUGUSTUS TROWBRIDGE.

Relativity referred to a Flat Space-Time.

As a preliminary communication, I wish to indicate briefly a few main results which could be made the starting-point of a general theory of relativity which shall fit in, in a natural way, with the Newtonian scheme and older physics and shall avoid the necessity of formulating with Einstein a space-time continuum "curved" by the existence of matter. It would be sufficient, as we shall show, to adopt a space-time continuum which is "flat," for the formulation of physical laws.

Now let us write, in the usual form, the expression for the invariant interval between two contiguous point-events as

$$ds^2 = g_{\mu\nu}dx_\mu dx_\nu, \quad . \quad . \quad . \quad . \quad (1)$$

adopting Eddington's summation convention that whenever a literal suffix appears twice in a term, that term is to be summed for values of the suffixes 1, 2, 3, 4. The $g_{\mu\nu}$, of course, have to satisfy the necessary and sufficient condition for "flat" space-time, namely, the Riemann-Christoffel tensor

$$B^{\epsilon}_{\mu\nu\sigma} = 0. \quad . \quad . \quad . \quad . \quad (2)$$

Having thus defined the geometry we shall use, we shall show now how a consistent formulation is possible of the laws of mechanics, of gravitation, and of electro-magnetism, so as to conform to the general principle of relativity, still adhering to the fundamental concepts of "inertia" and of "force" and the invariability of mass, of the dynamics of Galileo and Newton.

Let us define the mechanical force acting on a mass-particle, by the tensor F^μ, as

$$mc^2\left\{\frac{d^2x_\mu}{ds^2} + \{\alpha\beta, \mu\}\frac{dx_\alpha}{ds}\frac{dx_\beta}{ds}\right\} = F^\mu, \quad . \quad . \quad (3)$$

where m is the mass of the particle, which is considered invariant, and c the velocity of light. This tensor, together with its associated tensors, shall form the mechanical-force tensor.

Now, on equating this tensor to zero, it easily follows that a mass-particle under no forces will describe a straight line in the space-time continuum; this, of course, corresponds to Newton's first law of motion, the law of inertia.

Then, turning to gravitation, we shall have to define the mechanical force due to gravitation acting on a particle. For this purpose let us define an invariant gravitation potential ϕ by the following tensor equation:

$$g^{\mu\nu}\left(\frac{\partial^2\phi}{\partial x_\mu \partial x_\nu} - \{\mu\nu, \alpha\}\frac{\partial\phi}{\partial x_\alpha}\right) = \rho_0, \quad . \quad . \quad (4)$$

where ρ_0 is the proper-density of mass which can be expressed by the equation

$$\rho_0 = \rho\frac{ds}{dt}, \quad . \quad . \quad . \quad . \quad (5)$$

where ρ is the usual density.

Then the mechanical force due to gravitation may be defined by the tensor G^μ as

$$-m\left\{g^{\mu\alpha}\frac{\partial\phi}{\partial x_\alpha} - \frac{d\phi}{ds}\frac{dx_\mu}{ds}\right\} = G^\mu. \quad . \quad . \quad (6)$$

This tensor, together with its associated tensors, shall constitute the gravitational force tensor.

Now let us see how the equations (3) and (6) reduce, under suitable conditions, to the equations of the Newtonian theory For this purpose we shall equate the expressions in (3) and (6). Then we have

$$mc^2\left\{\frac{d^2x_\mu}{ds^2} + \{\alpha\beta, \mu\}\frac{dx_\alpha}{ds}\frac{dx_\beta}{ds}\right\} = -m\left\{g^{\mu\alpha}\frac{\partial\phi}{\partial x_\alpha} - \frac{d\phi}{ds}\frac{dx_\mu}{ds}\right\}. \quad (7)$$

This, being a tensor equation, will hold for all co-ordinate systems if it holds for any. Therefore let us take the Galilean system for which the line-element is

$$ds^2 = -dx_1^2 - dx_2^2 - dx_3^2 + dx_4^2 \quad . \quad . \quad (8)$$

Now, as the equations of the Newtonian theory hold only for velocities small compared with that of light, we have, if we introduce this restriction, approximately

$$ds = cdt.$$

Then the equation (7) reduces, in the Galilean system, to

$$\left.\begin{aligned} m\frac{d^2x_\mu}{dt^2} &= m\frac{\partial\phi}{\partial x_\mu} + \frac{m}{c^2}\frac{d\phi}{dt}\frac{dx_\mu}{dt} \quad (\mu = 1, 2, 3) \\ \frac{1}{c}\frac{d}{dt}\left(\tfrac{1}{2}mv^2\right) &= -\frac{m}{c}\frac{\partial\phi}{\partial t} + \frac{m}{c}\frac{d\phi}{dt} \quad (\mu = 4) \end{aligned}\right\}, \quad . \quad (9)$$

where v is the velocity of the particle

Thus we see that if we identify ϕ with the Newtonian gravitation potential, the first equation of (9) gives the Newtonian equations of motion and the second equation of (9) leads to the equation of activity in a gravitational field Obviously we can identify ϕ with the Newtonian gravitational potential, for the equation (4) reduces for the Galilean system to the well-known form

$$\frac{1}{c^2}\frac{\partial^2\phi}{\partial t^2} - \nabla^2\phi = \rho_0 \quad . \quad . \quad . \quad (10)$$

We have thus brought gravitational force under the general principle of relativity by expressing it consistently in the tensor form. The second term of equation (6) is the essentially new feature of this theory, and it is curious to note that while it becomes insignificant in taking the space-components of the gravitational force tensor, it becomes quite significant in taking the time-component. The fact that such a term has naturally to come in can be seen by multiplying both sides of the equation (7) by $g_{\rho\sigma}\frac{dx_\sigma}{ds}$ and contracting the product to an invariant, when both sides become zero. It may also be seen that the choice of a gravitational force tensor seems to be limited as we have at our disposal only ϕ, $g_{\mu\nu}$, and $\frac{dx_\mu}{ds}$, and it does not seem to be possible to construct an alternative tensor degenerating to the Newtonian equations unless it be that G^μ of (6) is multiplied by an invariant differing little from unity. But there is no justification for doing this at present.

There is also a striking resemblance between the second term of G^μ of (6), which we shall call the "velocity" term, and the electromagnetic force tensor E^μ, which can be defined as

$$E^\mu = eg^{\mu\alpha}\frac{dx_\beta}{ds}P_{\alpha\beta}, \quad . \quad . \quad . \quad (11)$$

where e is the invariant electric charge and $P_{\alpha\beta}$ is defined by the equation

$$P_{\alpha\beta} = \frac{\partial k_\alpha}{\partial x_\beta} - \frac{\partial k_\beta}{\partial x_\alpha}, \quad . \quad . \quad . \quad (12)$$

where k_μ is the electromagnetic potential tensor, having for its components the three components of the vector potential and the one scalar potential of the electromagnetic theory. Now it is interesting to note that if we combine the mechanical forces acting on a charged particle due to gravitation and electromagnetic forces into a single expression, and if we take them for the Galilean system, the values for the "velocity" term of equation (6) fit in the diagonal of zeros in the following array for $P_{\alpha\beta}$, leaving the other values of the array unaltered

$$\begin{array}{cccc} P_{\alpha\beta} = 0 & -\gamma & \beta & -X \\ \gamma & 0 & -\alpha & -Y \\ -\beta & \alpha & 0 & -Z \\ X & Y & Z & 0. \end{array}$$

Thus we have shown that if we adopt the scheme of equations given above, we can return to the mechanics of Galileo and Newton, with the suggested alteration in the law of gravitation, still holding fast to the ideas of inertia and force and the invariance of mass, without being obliged to make mass dependent on velocity and to obliterate the difference between mass and energy as the special and general theories of relativity would lead us to believe, of course, the variable inertia of electrons at high speeds could well be seen to follow from equations (3) and (11), leaving the notion of the invariability of mass intact

The Biology of the Suez Canal.

THE Cambridge expedition, financed by the Royal Society, which left England in September last to study the migrations of marine organisms through the Suez Canal (see NATURE, vol 114, pp. 520, 866) has returned on the Orient liner *Ormuz* The members of the expedition were Messrs H M Fox, R Gurney, V. C. Robinson, and D N Twist The full results will naturally not be known until the collections have been worked out, but certain general conclusions can already be drawn

Since the communication to NATURE of December 13 last, the central and northern portions of the Canal have been studied Lake Timsah in the middle region of the Canal near Ismailia is characterised by great variation in salinity, unlike the Great Bitter Lake farther south where a high salinity is constant In the centre of Timsah, with a south wind and a current to the north, a density as high as that of the Great Bitter Lake is recorded In other circumstances the density in the same situation is much lower At the edges of Timsah, and in the lagoons communicating with it, all intermediate degrees of brackish water to pure fresh are found The fauna in various portions of the lake is consequently diverse, and in the situations where rapid salinity changes occur must be resistant to these.

It is remarkable that whole large groups of animals, such as anthozoans, echinoderms, brachyuran crustaceans, ascidians, etc, which were absent from the Canal in 1882, are now abundantly represented. Yet the Canal was opened in 1869, and certain forms such as barnacles and cockles established themselves in the region of Lake Timsah from the very commencement. Why then did these other groups migrate in so late? In Lake Timsah the contrary phenomenon is found in the case of Mytilus and Pholas, previously very common, now absent. An attempt is being made to correlate these arrivals and departures with changes in the Canal at different dates. The late immigration of the crab *Neptunus pelagicus*, for example, which started from Suez in 1893 and reached Port Said in 1898 (NATURE, vol. 113, p 714), coincides with the first widening and deepening of the Canal. Again, when the water samples brought back by the expedition had been analysed and compared with past data, the proportions of the dissolved substances in the waters of the Bitter Lake may be found to have altered at a certain period owing to the upper layers of the bed of salt which forms the bottom of the lake becoming dissolved. Such a change could affect migrations But it must be remembered that in general very little is known about the causes of the migrations of littoral marine animals On a sand flat opposite Port Taufiq, Suez, for example, the writer observed large numbers of Synapta in 1920. At the same season in 1921 the ground was covered in addition by quantities of immature Centrechinus. In 1924 both were absent, although the conditions were apparently unaltered

Between the Bitter Lakes and the Gulf of Suez the currents in the Canal are tidal, reversing their direction twice daily, and they are rapid Between the Great Bitter Lake and Port Said the currents are slow and seasonal, flowing to the north for ten months, to the south for two only, namely, August and September The consequence is that the salter water from the Great Bitter Lake extends north to within 40 km. of Port Said (the total length of the Canal is 160 km, and the distance from the Bitter Lake to Port Said 98 km) during ten months, while the less dense water of the Mediterranean penetrates south beyond Lake Timsah (to a distance of 90 km from Port Said) during two months only. The results of this are, first, that for most of the year there is a barrier to the penetration from the Mediterranean of forms which cannot support very salt water, and second, that the salter environment of the Bitter Lake extends far to the north for most of the year with the following possible consequence The fauna of the Bitter Lakes was found to be richer than that of the seas at the mouths of the Canal, but from a study of the Lakes alone it was uncertain whether the favourable factor is a more suitable bottom or the higher salinity. Now between the Great Bitter Lake and Port Said there is a rich fauna on the piers just as far north as the salter water extends during ten months, while between this point and Port Said the pier fauna is noticeably poorer. The substratum is the same throughout, but the salt-content of the water different.

The final field work consisted in an examination of the fauna and flora of Port Said harbour. Further, the bottoms of tugs and barges which had been employed at one end of the Canal were scraped as soon as they moved to the other end, and again after they had been there some time, in order to see what forms could remain alive in their new environment and possibly could have established themselves there in the past, brought through the Canal on the ships' bottoms.

An important side of the work is necessarily incomplete because a part of the Canal fauna is seasonal in its appearance or in its breeding. Large Aurelia-like medusæ, for example, are so common in August that they foul the screws of motor boats, yet they were not found by us. Many animals breed at a different period of the year, so that we will be unable to give a general answer to the important question

of whether this or that form breeds in its new environment or merely migrates in from the sea during the lifetime of the individual. These matters should be further studied by a future expedition working in the spring instead of the autumn

In conclusion, we would like once more to thank the Canal Company for their great generosity in providing lodging and boats and for the unfailing help and kindness of their employés. At the same time we must repeat our thanks to the Egyptian Government, in particular to the Coastguards service, for their very willing assistance H. MUNRO FOX

Short-period Variations of the Wind.

IF one examines the autographic records of wind velocity and direction obtained at any inland observatory on a summer's day, it will be found that both traces are markedly different during the day-time as compared with the night An occasion on which this effect was very well developed is represented in the traces obtained at Porton on July 5-6, 1923 The anemometer vane is mounted at a height of 13·5 metres and has an excellent exposure. The direction chart shows that during the day-time the wind is characterised by very large variations in direction These variations are, moreover, of a peculiar type It is observed that the wind assumes a fairly steady and definite direction for an interval of the order of ten minutes. It then suddenly swings through an angle of perhaps 60° or even 90° After maintaining this new direction for some minutes, the wind shifts again with equal suddenness Regarded as short-period variations, these shifts are quite irregular in occurrence, although when considered over a period of some hours, the mean direction agrees with that demanded by the pressure gradient In contrast with this behaviour we may compare the trace obtained during the night This is the normal type of trace in which deviations from the mean direction are both small in amplitude and of short duration. The wind velocity record also shows a characteristic effect during the day-time short intervals of nearly dead calm alternate discontinuously with intervals during which the velocity is nearly constant with a value of two or three metres per second It may be noted that the durations of these lulls and gusts are about the same as those of the changes in wind direction. At night-time the velocity trace becomes normal like the direction trace.

The effects described above are much more marked in summer than in winter; they occur during the day and not during the night; and the stronger the sunshine the more pronounced the effect. Moreover, an examination of the Shoeburyness records shows that the phenomenon is strongly developed in off-shore winds, but only very slightly in off-sea winds.

Attempts to explain this phenomenon in terms of the interchange of masses of air at different heights appear to be unsatisfactory for the following reasons. In the first place, observations at Porton tend to show that lulls of this type extend from the ground up to a height of at least 15 metres, and it is difficult to understand how a thin layer of air lying on the ground can be extended to this height. In the second place the experimental evidence seems to indicate the non-existence of descending currents which would be adequate to cause the gusts. In this connexion Mr. C. E. Britton has kindly examined the pilot-balloon observations made at Shoeburyness, and he finds that, under conditions of strong convection, descending currents are conspicuous by their absence. (The vicinity of cumulus clouds is, of course, not being considered.) Thus in all probability the cool descending currents are comparatively slow and are spread over wide areas In this event they will not retain their initial high velocity in the manner necessary to produce the observed gusts.

As an alternative to this explanation, it occurred to Mr. O. F T. Roberts and the writer independently that the phenomenon might be caused by small travelling zones of reduced pressure. Such areas of reduced pressure are presumably to be found at the base of columns of ascending air on days of strong convection. The inflow of the surrounding air towards such centres will necessarily constitute miniature cyclones These miniature cyclones will travel with the general air movement, and their passage will produce, on the present view, the particular type of gustiness which we are here considering. Thus, if one of them passes an anemometer so that its own circulation assists the general air movement, then a gust will be produced, and similarly if its circulation opposes the general air flow, then a lull will result It will also be seen that the passage of miniature systems of this type will give rise to the particular kind of direction variation which is associated with this form of velocity gustiness

Considering the duration of this type of gust in conjunction with the wind velocity, it appears that a common value for the " diameter " of these miniature cyclones is of the order of a kilometre By the aid of Ferrel's equation, it is possible to calculate the reduction of pressure necessary in one of these systems to produce a gust of 2 metres per second in an otherwise still air In this case the cyclostrophic term is far more important than the geostrophic term, and it is found that a pressure difference of about one-twentieth of a millibar is required. Conditions corresponding approximately to this case occurred between 1100 h and 1300 h on the date already referred to The microbarograph trace for the same period shows quasi-periodic variations of about one-twentieth of a millibar, and of roughly the same " frequency " (about 8 to 10 per hour) as the gusts Similar results are found on other days of strong sunshine and light winds

It is interesting to observe that, since the geostrophic effect is so small in pressure systems of this size, the direction of circulation within them will not necessarily always be that of full-sized cyclones in the same hemisphere The direction of rotation will rather be determined by the initial velocity of some part of the air which goes to form the new miniature cyclone. For this reason gusts and lulls will sometimes be accompanied by temporary veerings in the wind direction and at other times by backings

Interpreted in terms of eddy-diffusion, the effect described above may be regarded as implying a very large value for the horizontal components of the coefficient of eddy-diffusion if considered over a long time interval. But if considered over a period of say half an hour, then the effect can only be regarded as irregular. The special characters assumed by the wind velocity and direction in these circumstances may also be regarded as special types of variation in the longitudinal and lateral components of the wind It is a matter of some interest to ascertain whether, under the same conditions, the vertical component of the wind acquires any corresponding peculiarity. Although it has been shown by Taylor (Advisory Committee for Aeronautics, Reports and Memoranda, No. 345) that in general the longitudinal, lateral, and vertical components of gustiness are

approximately equal, it was thought worth while to construct an instrument which will provide continuous records of the vertical component of the gustiness of the wind. Such an instrument is now in operation at Porton, and it is hoped that it will throw further light upon the nature of the short-period variations of the wind near the earth's surface.

Estimating the Qualities of a Photographic Plate.

THE testing of photographic plates presents to-day a number of complexities, and is so wholly unsatisfactory from a technical point of view that two special meetings have been convened by the Royal Photographic Society, held on January 7 and February 10, at which discussions have been held, and suggestions made, by leading authorities for a better system of estimating the speed and general characteristics of sensitive emulsions A special committee has also been appointed to consider the suggestions resulting from these discussions, which are to be forwarded to an international gathering in Paris next June, where it is hoped that some new system may be generally agreed upon

The accepted method of plate-testing, devised by Hurter and Driffield in 1890, is to expose sections of a plate to a standard light source for times increasing geometrically, and after development under standard conditions to measure the densities of these strips and to plot them as ordinates against log exposure The result is a curve of the well-known form shown in Fig. 1, *PQRS*. But with the very great increase in speed of modern plates these "characteristic curves" often show a type of curve like *XYZ* in Fig. 1.

In curve *PQRS*, *PQ* is termed the under-exposure

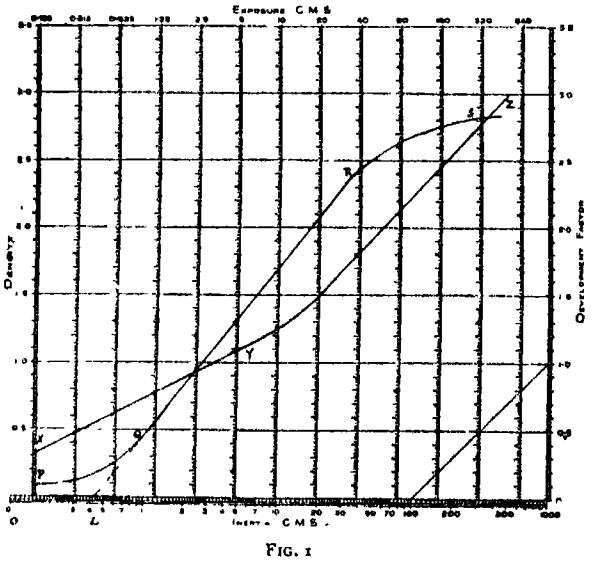

FIG. 1

portion, *QR* the straight-line portion, representing the "period of correct exposure," and *RS* the over-exposure portion. With many high-speed plates *PQ* stretches out to *XY*, *i.e.* the under-exposure portion becomes straight, and indeed most studio negatives as made by the professional photographer of to-day utilise only this part of the curve; on higher exposures the curve may jump upwards, as shown by *YZ*, such a plate giving good density in the extreme "high-lights," but soft, uniform gradation in the half-tones and "shadows."

If the straight-line portion of curve *PQRS* be produced to cut the log exposure axis at *L*, *OL* represents the inertia of the plate, and its reciprocal represents the speed; $34/OL$ gives the accepted H. & D. speed number.

Nietz has, however, shown that if several plates,

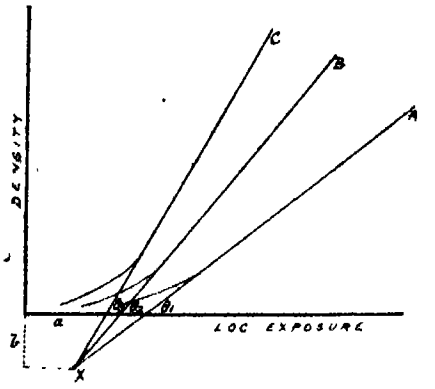

FIG. 2

given the same exposure, be developed for different times, and their curves plotted, such curves, *A*, *B*, and *C* for example in Fig. 2, may intersect at some point *X*, *below* the log *E* axis if there is free bromide present in the silver bromide emulsion, as is almost invariably the case. In such a case the inertia, as seen, will vary according to the time of development, and he suggests using the co-ordinates *a* and *b* in making the speed determination.

The contrast-giving power of the plate is measured by the steepness of the curve, and is called the development factor, γ. This is proportional to tan θ, and clearly γ will be different for different times of development, being $k \tan \theta_1$ for *A*, $k \tan \theta_2$ for *B*, and $k \tan \theta_3$ for *C*.

Here, then, are some of the difficulties with which we have to deal, and on which some general convention is so urgently needed. Take curve *XYZ* in Fig. 1, for example. Shall we extend *ZY* to meet the log *E* axis to give the inertia, or shall we extend *YX*? Shall we plot a family of curves developed for different times, and use the co-ordinates *a* and *b*, where the speed number *H* could be obtained independent of the contrast-giving powers of the plate by using an equation of the form

$$\log H = \log k - a + b\ ?$$

Another difficult problem is to express the under- and over-exposure parts of the curve simply. *PQ* (Fig. 1) is of paramount importance to photo-engravers in the making of half-tone and line reproductions, as on it depend the "woolliness" of the dots and diffuseness of edge of a line. *PQ* and *RS* are of vital importance to the physicist where he is attempting to measure either light intensities or radiations by means of *density*,—the only portion of the curve that may be used is that in which log density/log exposure is absolutely constant; *i.e.* he must use *QR* only.

The wave-length limits of the light source also affect gradation to some extent, and some primary and secondary source of light, universally adopted, is most desirable.

The position may be summed up by saying that, in view of the very extended applications of photography to science and industry, and the extensive

use of half-watt lighting for studios by the portrait photographer, some fuller means must be found for expressing the characteristics of a plate and for interpreting its properties. T. THORNE BAKER

Excitation of Forbidden Spectral Lines.

HANSEN, Takamine, and Werner (*Kgl Danske Videnskab. Selskab Mathfys. Medd* 3) have observed the line $1S - 2p_1$ (Paschen's notation) of mercury in a condensed discharge, and Takamine and Fukuda (*Phys. Rev* 25, p 23, 1925) have found the line strongly developed in the glow of a branched arc We have excited this line, the corresponding line of zinc, and both $1S - 2p_1$ and $1S - 2p_2$ of cadmium in the positive column of a hot-cathode discharge. The positive column was viewed end-on while the cathode glow was confined to a side tube. The potential difference across the entire tube was of the order of 100 volts, but the tubes employed were of such length, 30 to 100 cm., that the voltage drop per mean free path of an electron was quite small. The spectrum is strictly of the arc type, only a few of the more readily excited spark lines appearing, and these in comparatively low intensity

The cadmium lines, λλ 2230, 2267, 2307 and 2329, were sharply absorbed by the positive glow, a spark under water or discharge in a hydrogen tube being used as the continuous background These lines have been independently classified by both Ruark and Paschen (unpublished) as belonging to the group $2p - 2p^1$. Other members of this group involving transitions from the $2p_1^1$ level were definitely not present in absorption An unknown line at λ3086·7 appeared on some of the exposures as a weak but sharp absorption line

Radio Reception on Frame Aerials.

EXPERIMENTS in the reception of medium-powered distant broadcast stations on small frame-aerials of particularly small high-frequency resistance, with the use of correspondingly light reaction-coupling of the type usually associated with the name of Reinartz, appear to indicate that the commonly-accepted ideas as to the magnitude of the high-frequency voltages which can be registered on such aerials with small total tuning capacities across them, in these circumstances, require some modification.

With a frame of approximately circular form and 1 m. diameter, with 11 turns of thin bronze strip 6 mm. wide, spaced at 8 mm. in the form of a flat spiral (2 extra turns providing the Reinartz reaction-coil); and using a detector-valve and one transformer-coupled audio-frequency amplifying valve, both of amplifying factor M = 20, I was able to observe clearly intelligible speech and music from about thirty British and Continental stations, ranging from Aberdeen to Rome, in the course of one Sunday evening, in a quiet high point 35 miles N. of London, and on the first floor of a substantially-built house. Many of these stations, including the last mentioned, were later audible on a loud-speaker in a very quiet room; corresponding to a R.M.S. audio-signal-voltage of an average order of 0·3 volts. I had previously observed that, with an additional high-ratio transformer-coupled audio-frequency amplifying valve (three valves in all), at least two American broadcast stations could occasionally be heard, subject to the usual fading, on an even smaller aerial

The tuning and reaction-control were of an unusually fine order, and oscillation-hysteresis had to be carefully eliminated The signal-voltages observed here appear to be inconsistent with the usual estimates, and suggest also a revision of current practice in "radio-frequency amplification"

An Experiment with a Stroboscope.

ON page 543 of vol III of the "Dictionary of Applied Physics," an experimental arrangement is described where the stroboscope disc is illuminated by an intermittent light, using a neon-tube, an induction coil, and an electromagnetically controlled tuning-fork The same experiment can be performed in the light of an ordinary neon filled 110-volt Osglim lamp to which current is supplied from an alternating-current lighting circuit If the laboratory supply is of continuous current, then the arrangement can be considerably improved with the use of a rotary convertor the speed of which can be regulated so that the frequency of the intermittent light can be ascertained directly with a speedometer and stop-watch. As a demonstration experiment this arrangement is particularly convenient, since both the stroboscopic disc and the frequency of the source of light can be varied at will, and very interesting effects may be observed G R PARANJPÉ

The Crisp Collection of Microscopes.

MAY I add a note to the brief statement referring to the Crisp collection of microscopes in NATURE of February 14, p 241? Doubtless it is true that on occasion the late Sir Frank Crisp may have led the authorities to believe that he contemplated leaving his collection to the Science Museum at South Kensington, but it is equally true that his chief desire was to see his collection used for the preparation of a comprehensive history of the microscope in amplification of Mayall's Cantor Lectures, printed in 1886 Some years ago he asked me whether I would be willing to compile such a history, and he gave me a few notes on his instruments for the purpose Last week I received a letter from my friend Prof Poulton, in which he recalled a conversation with Sir Frank Crisp. "I remember his telling me that he did not know what to do with it (the collection), and I tried to persuade him to leave it to the Pitt Rivers Museum. If the collections now in the Old Ashmolean had been there, then I expect he would have left it to Oxford" This I believe to be the truth Sir Frank Crisp did not desire to duplicate the series in the possession of the Royal Microscopical Society, or that his collection should be merged in a larger one, and only be partly exhibited. But the facts that many of the parts of the instruments have got mixed, that historic examples have been divorced from their history, that the collection has been distributed without having been properly catalogued, is an international calamity.

The Investigation of the Properties of Thin Films by Means of X-rays.[1]

By Sir WILLIAM BRAGG, K.B.E., F.R.S.

THERE are a number of problems of the highest importance which are, or can be, contained in the study of what we often call the "thin film." They are linked together by the fact that most reactions between bodies are largely determined by what takes place at their points of contact, and therefore by the nature of their surfaces. What is to be found in the interior of the body is often of much less importance than the composition and state of its surface film. The immensely varied problems of surface tension are examples of one kind; the phenomena of catalysis, of friction and lubrication are examples of other kinds.

Though the thickness of the surface film is so important, it is often very small—beyond the limits of direct optical measurement. The X-rays measure more minute quantities than the microscope, and we may well ask if they can carry us any further. They measure only, it is true, the spacing of a stratification, and a stratification cannot consist of a single layer or film: so that the rays cannot be applied directly to the examination, for example, of the black spot on a soap film. But they are able to help in an indirect yet effective way. For they deal with problems of the arrangement of molecules, and all these manifestations of surface action are directly dependent on the arrangement of the surface atoms and molecules. Also the substances, the actions of which in single thin films are of great interest, are often found multiplied into crystals which actually can be examined by the X-rays.

The soap bubble and soap film have long been studied for their beauty and their interest. Since they have so large a surface in comparison with their volume content, they offer special advantages for the examination of surface actions. Yet they are so full of detail that even with the last few years new and most interesting discoveries have been made with respect to them. It will be convenient to review some of these briefly as illustrations of the facts that have to be accounted for.

When the bubble is near its end a black patch often appears, and soon afterwards the bubble bursts. The patch is black because it is so thin, and therefore reflects little light. It might be thought that the "black spot" represents a breakdown in the structure, a forerunner of collapse. But it is in reality a relatively stable affair: in proper circumstances it can be maintained for hours and days, as Sir James Dewar loved to show. Reinold and Rucker, Rayleigh, Johannot, and many others were greatly interested in the sharpness of its outline, its thinness, and the uniformity of its texture. They recognised two degrees of blackness, as Newton had done long before; they supposed them to represent a single film and its duplication. They succeeded in measuring the thickness, and estimated it to be about 60 Angstrom units in the case of the thinner and twice as much in that of the thicker.

When a film is correctly prepared and mounted, the black spot appears at once at the top of the film, a horizontal line separating it sharply from the rest with its horizontal bands of colour. Small black spots are continually forming at various points of the coloured film and rushing up to join the main spot: it is, of course, the downward movement of their surroundings which makes them move in the opposite direction. Sometimes minute points of light like stars appear, moving about on the surface and especially at the edges of the black spots—drops of water apparently.

When observations of this kind are made in the quiet of a laboratory, with small and more manageable films and with special instrumental facilities, a fineness of detail is revealed which cannot be followed on the screen. Our knowledge of these details is due to the beautiful work of Perrin, published in 1918, and to its repetition by Wells in 1920. To state Perrin's results very briefly, it appears that the two degrees of thickness first observed are due to the existence of a very thin uniform film and its doubling, as had already been shown, that the existence of three more degrees of blackness observed by Johannot was due to further repetitions of the same layer, and that a close examination revealed the existence of dozens of these layers, all multiples of the same fundamental thickness. In the blackest spot there was but one layer, and this was, strangely enough, the most stable of all. Other similar layers could be found superadded, like sheets of paper of the same uniform thickness, until the film was thick enough to show the rich colours of Newton's rings which the soap film ordinarily displays. As we know, the colour of the film is an indication of its thickness. For example, the colours proceed from black through greys, becoming lighter and lighter as the thickness increases, then to a nearly pure white, then through straw-yellow, yellow, orange-red, dark red to a violet, which always changes very quickly with alteration of thickness, and so forms a definite stage. The thickness has now reached (for water) about 2100 Å.U. Perrin counted 37 to 38 steps by which the superimposed sheets mounted to the full thickness that gave the violet tint. He made measurements also with monochromatic light and as his final result arrived at the conclusion that the thickness of the single film was about 52 Å.U. Wells found a somewhat smaller value, namely, 42 Å.U. Perrin, and Wells after him, concluded, on evidence which we have not time to consider, that the single film was composed of a double layer of oleic acid, arising from the hydrolysis of the sodium or potassium oleate in solution.

Now Rayleigh, Devaux, and more lately Langmuir, Hardy, and Adam have measured the thickness of an oil film spread on the surface of water. It appears that in the case of a fatty acid such as stearic or palmitic, when the surface is fully charged, the long chains stand on end, their carboxyl terminals rooted in the water, for which they have a great attraction, and their methyl terminals are turned outwards. The length of the oleic acid molecule is about 23 Å.U. It is clear that this length can easily be in agreement with the suggestion made by Perrin. His film of 52 Å.U., or 42 Å.U. according to Wells, would consist of two layers of oleic acid molecules, the carboxyl ends meeting in the centre. The molecules are held together, side by side, to form a strong sheet, while the methyl groups form a surface reacting very slightly with anything outside.

[1] Discourse delivered at the Royal Institution on Friday, January 16.

The examination of crystal forms by means of X-rays shows that the peculiar arrangement of the molecules in these films on water extends also to the solid crystal in a great number of cases, and may probably be considered as characteristic of the structure of a large and important class of substances It is in the first place to be found in the solid forms of the fatty acids, hydrocarbons, alcohols, and other long-chain molecules These have been examined by Piper at Bristol, and by Muller and Shearer in the Davy Faraday Laboratory I referred to a few of these a year ago The number examined has been largely increased during the last twelve months, and the results that have been obtained are ready for publication

When a small quantity of one of these substances is placed upon a plate of glass or mica, either by melting or by pressing, a formation of layers results, much more so by the latter operation, for it would appear that the pressing and working encourage the arrangement of the molecules and the regularity of the layers that are formed The material is now placed on an X-ray spectrometer, and a photograph is taken by the method of the revolving crystal The photographic plate shows usually a number of lines which clearly represent the orders obtained by reflection from the plane of the layers. In this way the thickness of the layer can easily be measured with an accuracy of about 1 per cent Ten or more orders are often observed. The cleavage plane of many crystals, especially of the class I am describing, often gives several orders, but not usually so many as in this case. other reflecting planes may give only one, perhaps two, higher orders of moderate strength, more often only very weak reflections, except in the first order. No doubt the case is parallel to the well-known effect in optics, where a grating yields many orders of spectra when the lines are sharp and fine. The "line" in this case is a well-defined discontinuity in the distribution of scattering centres which occurs at the ends of the long molecules, a defect would be caused by the presence of the hydrogens of a methyl group, an excess by the oxygens of a carboxyl group. We may suppose the planes which separate layers of these molecules to be well marked in this way, and that otherwise there is a fairly even distribution along the body of the molecule.

If we plot the spacing of each substance of any one series against the number of carbon atoms in the chain, we find at once that the indicating points lie exactly on a straight line, except when the chain is short. This has been proved by Muller and Shearer for the fatty acids, hydrocarbons, alcohols, ketones, and in other cases, and the regularity of the results leaves no doubt as to facts. The increase for each carbon atom is either about 1·0 Å.U. or 1·3 Å.U, the former occurring in the fatty acids, for example, and the latter in their esters.

If we may assume that the molecules lie perpendicularly to the layer, the numbers found for the thicknesses are actually the lengths of the molecules, and there is some ground for supposing this to be often true. But, of course, the molecules might *not* be normal to the layer, in which case the length of the molecule would be more than the thickness of the layer. It is certain that this may sometimes be so. Small crystals of substances of this class have been obtained and successfully measured in these laboratories by R E. Gibbs, in spite of the fact that they each weighed only about a hundredth of a milligram. Gibbs finds that the crystals are of monoclinic prismatic form

In this instance, then, the molecule is not upright but sloping. It is difficult to imagine that the molecules all slope one way in the oil films on water, there would surely be some unique and recognisable direction in the film. It is possible that the explanation may be found in the fact that there are actually two ways, perhaps several ways, in which the molecules arrange themselves Gibbs has found an orthorhombic as well as a monoclinic form, and Muller has observed that a hydrocarbon gives a somewhat different value for the spacing when it is only a few degrees below its melting-point The physical appearance is different in the two cases. In the latter the film is translucent in the usual case it is opaque, probably on account of minute crevasses formed during shrinking This may be the cause of the change we see passing over cooling candle grease: it is transparent one moment, and suddenly clouds over

The inclination of the molecule to the plane of cleavage must be finally settled before we are quite sure that we are measuring the actual lengths of the molecules, but we may hope for an early solution.

The fatty acid molecules are in double layers, but the hydrocarbons are not We know this in two ways In the first place, the actual increase in length for each carbon atom is twice as great in one case as in the other. In the second place, the even orders of the fatty acid spectra are very weak compared to the odd orders

Such an effect can be produced in an optical grating by an alternation of white and black lines on a grey ground. An alternation of strong and weak black lines gives strength to the even orders substituting white for one of the blacks is equivalent to changing the sign of its contribution Gratings can be so made as to illustrate the point If molecules pointing opposite ways are joined by their carboxyl terminations, then the methyl ends of the molecules are weaker in scattering centres than the general average along the molecule, but the parts where the carboxyl groups join together are above the average in strength

Shearer finds another illustration of this effect in the case of hydrocarbons which form a single layer, but are converted into ketones by the substitution of oxygen for hydrogen at some point of the length When the substitution is at the middle of the chain, there is at that point an excessive number of scattering centres, and we have again the circumstances that cause reinforcement of the odd orders. But if the substitution is not at the middle of the chain, the odd orders are no longer strong compared to the even.

We have, therefore, in these stratified layers which we are examining by the X-rays, the very same formation that Perrin has observed in the liquid films. The molecules are found, without exception, to be extended to their full length, and linked together by their carboxyl terminals. Shearer finds the length of the double molecule of oleic acid to be about 36, which is to be compared with the 52 of Perrin and the 42 of Wells.

The conditions which lead to the formation of films on a water surface, and layers in the fatty acids and similar bodies, are operative also in the case of a large

number of more solid crystals. A certain flakiness is the result, the crystals cleaving very easily into thin layers which slide readily on one another, and often give a greasy feeling to the crystal.

Naphthalene and anthracene are cases in point. Their molecules are long and narrow, and are arranged side by side like the oleic acid molecules on water. A single layer is like the corn in a field; but they lean over like the corn when a wind is blowing. They are not perpendicular to the layer. The bonds that tie the molecules side to side must be stronger than those that tie them end to end, because the flakes are so easily parted from one another. The naphthalene molecule contains two hexagonal rings of carbon atoms and the anthracene molecule is extended by the addition of a third, so that the layer is thicker in the latter case In both cases the molecule has a centre of symmetry, and in each layer the molecules are divided into two classes in respect to their orientation. Any member of one class is joined up by ties of some sort to several (probably four) members of the other class, which immediately surround it in the flake; and it would seem that this cross linking holds the flake together and gives it its strength

It is likely that a very large number of other substances are built on the same plan Even when their examination has not yet been attempted by means of X-rays, their crystallographic measurements suggest the fact.

In other substances a similar external form is attained by a somewhat more complicated internal arrangement. The molecule has of itself no centre of symmetry, in fact no symmetry at all, and twice as many are required in the construction of the monoclinic prismatic unit of pattern. This is the case, for example, with benzoic acid, and probably with many of its derivatives But there is the same flakiness which may be put down to the same causes: (1) the general orientation of the molecules so as to lie across the flake, and (2) the hydrogen terminations In all these cases we find that the crystal is tied together by links extended from each molecule to neighbours of the other possible orientations: this seems to be an essential feature of crystal construction. It cannot, of course, be followed in the lowest type of crystalline symmetry, where there is but one orientation possible, and every molecule is arranged exactly as every other. But though this arrangement can be conceived, it is doubtful whether there is a known case it has been shown by Astbury that calcium thiosulphate, generally quoted as the solitary example, has probably the symmetry of Class 2, which contains two orientations, connected by a centre of symmetry Whether this is so or not, it is certain that in at least the vast majority of cases, cross linking is an important feature It may very likely be a factor in the determination of the faces that appear on a crystal A face will naturally contain specimens of more than one molecular orientation, so that the elements of the face may be tied together strongly. For example, in naphthalene, as in many other cases, all the usual faces contain equal numbers of molecules of the two orientations. one might even predict the arrangement from the knowledge of the form.

If, therefore, we survey the general characteristics of this large class of flaky crystals, we observe that the monomolecular films of Langmuir and the multiple stratifications of Perrin, and the whole range of "thin films," have much in common with the solid members of the class. Yet there are significant differences. It seems possible by studying both resemblances and differences to obtain some fresh light on the properties of the more "liquid" films.

With these facts before us we may perhaps formulate a more detailed theory of the black spot on the soap film. The ordinary thick film is bounded on each side by the monomolecular film of oleic acid. In this film there is certainly arrangement. Adam, in particular, has examined the compression of the film under applied forces, and his observations and conclusions fall in naturally with the ordered array that we should expect to be there. But the film is imperfectly crystalline. It is compressible up to a certain point, and during the range of compression may be considered as a two-dimensional gas. The perfect crystal of this class of substance is found in the films studied by Muller and Shearer, and in the minute crystal which Gibbs has measured. The perfect crystal of oleic acid contains twice as many orientations as the film of oleic acid on water: the molecules on the water are only one way up, and the reversed molecules are required to complete the structure.

Suppose, however, that the oleic acid films on the two sides come into contact anywhere; the conditions for the completion of the crystalline structure are now all present. The carboxyl groups not only meet, but interlace: each molecule in the upper group linking together two or four molecules in the lower, and vice versa. This is doubtless a far more stable form of arrangement than that of the single film. The two outside single films, once united in one place, must increase their area of contact, and will drive the expelled water before them until the accumulating heap becomes too great for them to push any further, the action being assisted by the tension of the rest of the film

The film thus formed is a real crystal, because it contains all the molecular orientations. The black spot is simply the thinnest possible flake of oleic acid. It is true that oleic acid melts at 11° C., but the crystalline structure is there, in a mobile state. Solution cannot be made to enter between the two surfaces now united in crystalline fashion. Other films may be formed and float about on it, holding on by virtue of the feeble attractions of the methyl groups on one another: even the pressure of the air must help in keeping them together. These added films will slide about easily; they also will be true crystals of oleic acid, probably without any water.

The differences between the conditions and structure of the black spot on one hand and the neighbouring thick film on the other are so great that we may cease to wonder at the sharpness of the boundary and the enormous change in thickness: on one side of the boundary the thickness may be hundreds of times as great as on the other.

When the black spots appear and rise through the thick part of the film to join the general black area at the top, they leave trails behind them: they look like tadpoles swimming up to the top of the water. When the motion becomes less violent the tails shrink into small circular spots. On the other hand, if a thick

patch is forced by the general turmoil into the middle of a black film, it tends also to a circular shape.

We come now to another of the important surface effects, namely, that of friction, or, stated inversely, of slipperiness These flaky substances are in general slippery and greasy to the touch. The greasy feeling seems to be due to the ease with which the flakes are split from the main body of the substance, and then slide over it. Graphite is an extreme example of the flaky state: and without forcing its inclusion in the class of substances we are considering, we observe that the atoms in each flake are tightly tied together, and that there is a very weak linkage between a flake and its neighbours It is the combination of these conditions that makes for good lubricating qualities. Now in these substances the same conditions hold to a greater or less extent: the molecules of stearic acid, for example, are tied together more tightly side to side than across the ends at which the methyl groups are attached. If, therefore, stratification exists to any considerable degree, the same consequences follow as in the case of graphite. In general, stratification is incomplete, which is another way of saying that a large perfect crystal of stearic acid is never seen. Pressure is one agent that causes stratification, so that if one presses a piece of stearic acid or other material, the very pressure produces the conditions for easy slipping. I have already mentioned that Shearer and Muller have often found that a portion of the material melted on to a piece of mica or glass, and placed on the spectrometer in the necessary position for giving reflections from planes parallel to the glass, was comparatively ineffective in this respect. It would give clear evidence of those two spacings which are found on all the plates, and are ascribed to the widths of the molecules and are independent of their lengths. When the specimen was pressed, or rubbed down on to the plate, the stratification spacing appeared at once, and the others disappeared, thus showing the nature of the rearrangement that had taken place. It may be that this effect explains other properties of greases. I am told that the special grease used in binocular fittings is made serviceable by working with a palette knife

We must recognise, however, that the layers built into the crystal are not at all times ready to slide, otherwise a mere tilt of the crystal would cause them all to slide off one another like a pack of cards. There is a sticking friction to be overcome, exactly as in graphite. It is only possible to speculate as to the cause · perhaps it is a real molecular effect, and sliding only occurs when the bonds, weak as they are, are further weakened, as if the substance was about to melt: perhaps it is rather a mass effect and due to imperfect crystallisation.

It seems not unlikely that, at its best, slipperiness in these cases is almost perfect. Between two perfectly formed methyl layers there is very little friction indeed, perhaps none at all. The methyl layer is seen at its best on the surface of the black spot in the soap film, and various writers have noted that one layer slides very easily over the other. Perrin, in fact, has directed attention to this remarkable effect, as shown in the Brownian movement of fragments of one layer, lying on and sliding over another.

In some of the experiments of Sir William Hardy and Miss Doubleday the condition of nearly complete slipperiness is attained Their beautiful researches on "boundary lubrication," that is to say, the slipperiness of very thin films, have established certain rules of surprising simplicity. They have found cases in which friction nearly vanishes, and in general accordance with the above, they frequently occur when a solid lubricant is practically wiped and rubbed off the surface, a true stratification in a very thin film being probably left.

Not only the phenomena of surface tension and of lubrication, but also those of catalysis, must be intimately connected with the actual arrangement of molecules. We speak of stereochemistry as showing the relations of the atoms in the molecules to one another, their mutual orientation and distances To deal with these subjects we shall have to extend stereochemistry to cover the mutual distances and orientations of molecules as well as of atoms. We see that we must not treat a molecule as if it were simply a sphere attracting according to gravitational laws: it is not even sufficient to speak of an atom in this way, except as an approximation in the case of ionic substances like rock-salt. If some super-Brobdingnagian inquirer were to argue from effects observed on the surface of the earth as to the nature of the human beings to which the effects were ascribed, and being unable to detect a single individual by the most refined methods of which he was capable, should say, "Let us provisionally assume the human being to be a sphere, having similar properties in all directions and no special points of attraction," he would not get very far towards a satisfactory explanation of his subject. It would be an advance should he recognise the existence of two types of opposite sign, and lay the foundations of an ionic theory of heteropolar assemblages, but even then he would fall far short of the truth In the same way, when we try to explain surface tension as the result of the mutual gravitational attraction of spherical atoms or molecules, we cannot make much progress Indeed, we sometimes arrive at consequences that appear startling, as when we determine their attractions by measuring the energy required to tear surface molecules away in the process of evaporation, and then proceed to deduce the existence of pressures of thousands of atmospheres within the body of a liquid. So we may measure the force required to tear away the fringing links of a piece of chain mail, take them to be due to mutual attraction between the links, and thence deduce the existence of an enormous pressure within the piece.

It is when we consider a catalytic surface as possessing active centres on its surface, the relative positions, magnitudes, and mutual distances of which are such that two wandering molecules of different kind, attracted by these points, may be held together in a special way, that we get some idea of the fundamental action of catalysis. It is important to consider, as the basis of surface actions, the arrangements of the molecules at a surface, both arrangements that actually exist, and those that are predisposed to exist This idea runs through all the work of those experimenters, Langmuir, Harkins, Hardy, Adam, Perrin, and many others who have made such progress of recent years: the X-ray studies emphasise this view and supply many quantitative measurements by which it may be shaped and strengthened.

Biographical Byways.[1]

By Sir ARTHUR SCHUSTER, F.R.S.

8. THREE GÖTTINGEN PROFESSORS, AND AN ADVENTURE.

WHEN I went to spend two months at Göttingen in the summer of 1874, Wilhelm Weber (1804–1891) had just retired from the professorship. I doubt whether the present generation of physicists are familiar with his work, though there was a time when electricians talked about weber-currents, galvanic-currents, and faradic-currents as if they were different things. I feel sure, however, that chemists have not forgotten Friedrich Wohler (1800–1882), who occupied the chair of chemistry at the University of Gottingen during forty-six years. Both men were Copley medalists Wilhelm Klinkerfuss (1828–1884) stands on a somewhat lower level of distinction, though he did meritorious work, was amongst the first to recognise the importance of Doppler's principle, and discovered six comets.

When Weber was first appointed to the chair of physics at Gottingen in 1831, that University formed part of the kingdom of Hanover. When its connexion with England was finally severed in 1837 by the accession of Ernest August to the throne of Hanover, the new king repudiated the constitution which the country had enjoyed for a considerable time. Seven professors of Gottingen protested against this autocratic action and had to leave the country They included, besides Wilhelm Weber, his brother, the physiologist, and Jacob Grimm, the writer of fairy tales Weber was offered a chair at Leipzig, where he remained until he was reinstated at Gottingen in 1849. In 1874, at the age of seventy, he was still full of vigour. A short man with a clean-shaven, round, and smiling face, he was ready to discuss the current scientific problems with freedom and sagacity I much enjoyed the two occasions on which he invited me to join him in his walks along the walls of old Gottingen

A man's mentality often finds significant expression in the way in which he shakes hands Kopp, of Heidelberg, used to raise the proffered hand slowly to the level of his short-sighted eyes, and keep it there for a few seconds as if wondering what to do with it. Weber raised his arm vertically upwards and swung it down in a swift and forcible sweep, as if he really meant it. I was told that, under the influence of Zollner, Weber had taken up spiritualism, but I never knew that side of him

In contrast with Weber, Wöhler seemed to live entirely in the past I only spoke to him twice, but while fond of relating old reminiscences, his conversation generally ended in a recital of his personal ailment. I can only remember one of his tales He had an official residence above his laboratory, and one night he was awakened by the noise of an explosion. He gave a graphic description how, with a candle in his hand, he went down to see what had happened. At the point of opening the door—he hesitated. Could there still be some explosive gases hovering round the laboratory? He blew out the candle and entered the room, and found indeed that he had narrowly escaped losing his life by a second explosion. There is not much in this story, but Wöhler seemed to be very proud of this testimony to his presence of mind.

I had called on Wöhler at the express wish of Roscoe, who sent him, through me, a small flask filled with vanadium salt. Wöhler was delighted, and could scarcely believe that this was for him to keep and not only to look at. He had been doing some work on vanadium himself with only a small quantity at his disposal, and on every occasion that I met him he always expressed surprise that Roscoe could spare so much of it. The day following my first call, on returning to my lodgings, I found a visiting card with his name neatly written on it.

Klinkerfuss was a man of different type and calibre. He generally took his meals in common eating-houses surrounded by students, and occasionally I was one of the party He used to entertain us with inferior jokes One example must suffice. "I have always had a remarkable memory for numbers," he said. "At school in the history lesson I could remember every date. Unfortunately, I always forgot what happened on the dates" It was said of him that when he received his salary he spent his money lavishly eating and drinking in the most expensive places, and when he had spent nearly everything he lived mainly on sausages and beer. His duties sat lightly upon him By a general rule of the German universities, a professor is not obliged to lecture to less than three students (*tres faciunt collegium*), and when at the beginning of term one of them called to inscribe himself for the course which had been announced, Klinkerfuss told him that he would have to find two others who also desired to attend. It was said that if half an hour later another man came with the same request, he received the same answer, and it was only when the term was in full swing that the disappointed students became known to each other. I do not vouch for the story. The facts that the fees go to the professors, and the well-known impecuniosity of Klinkerfuss, speak against it. He ultimately ended his life by committing suicide.

There was another professor at Göttingen, a philosopher and theologian, with whom I had some acquaintance When I called on him, he warned me that the life in Göttingen was different from that at Heidelberg. The students were more formal, and inclined to take offence if one did not conform with their codes of behaviour. It was not many hours before I had occasion to regret that I did not attach more importance to his warning The evening of my visit to him I went to some open-air place of entertainment where I met an acquaintance, who was accompanied by three other students. He asked me to join his party, but I told him that I was on my way home. Ultimately, he persuaded me to sit down for a few minutes. While I was talking to him I overheard remarks, made by his companions, about the impertinence of sitting down at a table without a proper introduction. I knew I was in for it, but awaited developments. Suddenly one of the men got up, placed himself right in front of me, clicked his heels together, and said, "My name is von

[1] Continued from p. 234.

Eberstein" (the names are imaginary). I gave him my name in return. After a minute or two the second man got up: "My name is Goldschmidt." I gave him my name. When the third man got up I fortunately remembered that I had a trump card to play, and after he had gone through his ritual I replied, "My name is Dr. Schuster," laying stress on the title. Whereupon all three silently left in a body. My degree was a sufficient distinction in rank to justify me in dispensing with the formality of asking for an introduction to them. I asked my friend what would have happened if I had not been a graduate: his reply was, that I should have had either to fight at least one duel or been treated as an outcast by German universities. All this happened fifty years ago, and must not be considered to apply to the present day.

Obituary.

SIR JAMES MACKENZIE, F.R.S.

BY the death of Sir James Mackenzie the medical profession and the world at large has lost a physician whose life was devoted to the advancement of our knowledge of practical medicine. His researches on diseases of the heart effected nothing less than a revolution in this branch of medicine, which had been stagnant for nearly a century

Sir James Mackenzie was born at Scone in 1853, and received his medical education at the University of Edinburgh, where he graduated in 1878 After extending his training by resident appointments in the Royal Infirmary he took his M.D. in 1882. Then followed twenty-eight years of busy general practice in Burnley, and it was during these years that he made the greater part of the observations which made his fame. It soon struck him, as it must strike many medical men, that for the diagnosis and treatment of a vast proportion of illness, his teachers had been unable to give him anything like adequate guidance Mackenzie, greatly stirred by discontent, set himself to the filling of some of the gaps, and two examples of this pioneer work may be mentioned The value of pain as a guide to diagnosis was realised when he found that it was referred from the offending organ to particular areas of the surface of the body through the agency of the nervous system, and that the organ was not itself painful. This fundamental change in the conception of pain was independently discovered and extended by Dr Henry Head. Another gap so brilliantly, almost completely filled, was the classification of the irregularities of the heart. For this purpose Mackenzie invented a clinical polygraph for recording not only the pulse but also simultaneously the venous pulse in the neck. It thus became possible for the first time to observe the action of the auricle, which proved a key to the elucidation of arrhythmia. Irregularities and murmurs were shown to be significant or insignificant by the rational, though laborious, method of following cases exhibiting them for years until their degree of importance became manifest.

Great interest was aroused at home and abroad by the immediate value of these discoveries, and when Mackenzie relinquished his general practice at Burnley in 1907 to take up consulting work in London, he was recognised as the foremost investigator and authority in the world on heart disease. His popularity as a consultant was not allowed to interfere with research, which was continued first at the Mount Vernon Hospital and later at the London Hospital. The action of digitalis in disease was studied to such purpose that, as Prof. Cushny has said, "more progress was made in fifteen years than in the preceding century." The impetus of progress was given to disciples from all over the world, and to them were opened fields of thought and work which seem sufficient for a generation.

When the War came, Mackenzie initiated through the War Office a special hospital for the elucidation of problems connected with "soldier's heart." In 1918 he retired from consulting work and went to St Andrews, where he founded the Institute for Clinical Research. He had realised that attention was habitually directed to fully developed disease, so that, as he said, patients seemed to be admitted to hospital when they had the physical signs of obvious disease and might almost be described as incurable He determined to study afresh the nature of symptoms as met with in practice, so as to learn of disease in its early and perhaps curable stage. As time went on, he foresaw that the phenomena of disease might be governed by simple laws which he formulated as a basis for further examination by his colleagues at the Institute. Then his health failed, but not his faith and courage, and he finally retired to London, where he died on January 26.

Mackenzie's personal qualities were an ornament to the greatness and originality of his mind, and endeared him to all his pupils. He was indefatigable himself, an inspiring and generous master, a superman, but none was more human. His personality will remain as worthy of admiration as was his relentless pursuit of knowledge, not only for its own sake but also for its application in the relief of suffering humanity

In 1911 Mackenzie was appointed physician to the cardiac department of the London Hospital. In 1915 he became a fellow of the Royal Society, and received the honour of knighthood; later he was appointed honorary consulting physician to the King in Scotland. His most important works are "The Study of the Pulse" (1902), "Diseases of the Heart" (1908), "Symptoms and their Interpretation" (1909), "Principles of Diagnosis and Treatment in Heart Affections" (1916), and "Angina Pectoris" (1923).

MR. WILLIAM WATSON.

WE regret to announce the death of Mr. William Watson, which occurred at St. Albans on January 30. He was well known in botanical and horticultural circles through his long tenure of the curatorship of the Royal Botanic Gardens, Kew, a position he held from August 1901 until June 1922

Mr. Watson was born at Garston, near Liverpool, on March 13, 1858, and received his first appointment at Kew in 1879, following several years' experience in trade establishments His knowledge of tropical and sub-tropical plants was probably unrivalled. For many years he was a regular contributor to the

horticultural press, and so long ago as the eighties of last century wrote a valuable series of articles on the Palmaceæ in the *Gardener's Chronicle*. These articles it was hoped might have been republished in book form as a monograph of this natural order, thereby bringing Berthold Seemann's work on the same family up-to-date. This hope, however, was never fulfilled. To vol. 15 of the *Annals of Botany* he contributed an illustrated paper "On the germination of *Bertholletia excelsa*," the Brazil nut.

In later years Watson took a keen interest in the Cactaceæ and succulent plants generally, and his "Cactus Culture for Amateurs" is the standard work on its subject. He also wrote books on "Climbing Plants," "Rhododendrons and Azaleas," and, in collaboration with W. J. Bean, "Orchids, their Culture and Management," all of which met with success On horticulturists in general he conferred a great boon by editing a new edition of "Thompson's Gardener's Assistant," so much improving it that it became practically a new work For upwards of twenty years he was editor of the garden section of the *Field* His life's work, however, was centred in Kew, an institution which owes very much to his forty-three years' devoted service. He was elected an associate of the Linnean Society in 1904

THE *Chemiker-Zeitung* reports the death on January 6, at the age of sixty-eight, of Dr. Wilhelm Borchers, professor of metallurgy and electrometallurgy at the Technische Hochschule of Aix-la-Chapelle. Borchers was born at the university town of Erlangen, and after completing his studies there, he spent the next four years in a chemical factory as process chemist. The experience thus gained was of immense value to him in his later career as an investigator, for it enabled him to bring to a successful conclusion many difficult researches in the field of electrometallurgy. In 1891 he was appointed lecturer in chemistry and metallurgy at Duisburg, and six years later he was transferred to the Hochschule at Aix-la-Chapelle. His chief interest lay in the application of electrolytic processes to metallurgical problems, such as the production of metallic calcium, strontium, titanium, cerium, etc. He also conducted numerous researches on the preparation and properties of alloys. Prof. Borchers was the author of several books on electrochemistry, and in 1894 he founded the *Zeitschrift fur Elektrochemie*, which he edited until 1900. He also collaborated with Nernst in publishing the *Jahrbuch der Elektrochemie*.

WE regret to announce the following deaths:

Prof Walther Dieckmann, of the Department of Chemistry in the University of Munich, on January 12, whilst carrying out a research in organic chemistry in the State laboratory

Miss Lilian Suzette Gibbs, known for her work on the mountain flora of Australasia and on problems relating to the geographical distribution of plants

Dr. E E Klein, F R S, formerly lecturer on advanced bacteriology in the Medical School, St. Bartholomew's Hospital, on February 9, aged eighty.

Current Topics and Events.

INTEREST in the therapeutics of consumption has again been roused by the reports of successful treatment, this time by a chemotherapeutic agent which, under the name of sanocrysin, has been investigated by Møllgaard, a professor in the Landbohojskole of Copenhagen. There is no mystery chemically about sanocrysin It is sodium aurous thiosulphate ($Na_3Au(S_2O_3)_2$) which has long been known as Fordos and Geles salt. Years ago it was shown that gold salts have a powerful action on tubercle bacilli *in vitro* and several gold preparations, simple and complex, have been tried therapeutically with indifferent success. Møllgaard affirms that sanocrysin inhibits the growth of tubercle bacilli in a dilution of 1 . 1,000,000 and that their progress may be completely arrested in a concentration of 1 · 100,000. In non-tuberculous animals sanocrysin is said to be relatively harmless, whereas in tuberculous subjects very stormy reactions follow its exhibition and may actually end in death. It is believed by Møllgaard that these violent effects are to be attributed to certain poisons, of a tuberculin character, which are liberated from the dying and dead tubercle bacilli from the action of the sanocrysin rather than to a direct toxic action of the thiosulphate. It is said that the violent reactions can be lessened or prevented by the administration of an anti-serum produced by the injection of tubercle bacilli or its products. The sanocrysin treatment is really a twofold process. There is supposed to be the direct bactericidal action of sanocrysin and the neutralisation of its poisonous results by an antitoxin of sorts. The Møllgaard treatment has been applied for a considerable time both in cases of tuberculous human beings and animals, but judgment must at present be reserved as to whether it is likely to occupy a permanent place in tuberculo-therapy.

IN the course of his fourth talk on "Ether and Reality" given under the auspices of the British Broadcasting Company at the London station, 2LO, on February 17, Sir Oliver Lodge discussed magnetism and its analogies with life and knowledge. Sir Oliver stated that electrification is a matter of transfer, a transfer of pre-existent charges, a disturbance of equilibrium. When equilibrium is established, opposite charges are close together and disappear from our ken. They never go out of existence: we neither create nor destroy. The same is true for magnetism: we can make a magnet, but the magnetism was there beforehand. Magnetic lines of force differ from electric lines in being always closed loops; all we do is to open them out. They tend to shrink, and thereby pull together two things round which they are looped, like an indiarubber ring. They never shrink up to nothingness. One magnet can produce any number of others, for there is no limit to the amount of magnetisation; what one body gains, the other does not lose. In that respect it is analogous with life. Knowledge in this respect is like life and magnetism: there is an unlimited reservoir from

which to draw, and the imparting of knowledge does not lessen the amount possessed by the imparter; it is transferred without loss, though doubtless with the expenditure of some energy Knowledge grows from more to more. By diffusion it is increased, what one gains, another does not lose A magnet which has excited other magnets may be even stronger than before; life which has excited other life may still be vigorous. So far as we learn from science, nothing goes out of existence, it only changes its form and may become inappreciable to our senses.

A COGENT restatement by Dr R P Scott of the case for co-operation between England and China on certain lines and under certain safeguards appears in the current issue of the *Contemporary Review* Those who are best acquainted with conditions in China are by no means so pessimistic as to the outcome of the present situation as the political news appearing in the Press might appear to demand Private advice from China, however, indicates that this news is by no means exaggerated and that the social and commercial situation is serious Dr Scott lays great stress upon the pre-revolutionary character of Chinese ideals in pressing that side of his argument which rests upon the fundamental similarities between the English and Chinese mentality These, he holds, find their most significant expression in the qualities characteristic of the English "gentleman" and the Chinese "princely man," as well as in business faculties, and in humour Granting that co-operation is both possible and desirable, of the various suggestions put forward there is much to be said in favour of education as the field Dr Scott points out that it is the only one in which continuity can be obtained, and further, it is one to which each of the parties brings something distinctive—the Chinese, a thoroughness of mental grasp, and the English, breadth of outlook. Without attempting to displace literary studies, we could add instruction in those branches of science, especially the higher branches of physics and of surgery, for which the racial characteristics of the Chinese are peculiarly apt, but in which at present they lack opportunities of training. Dr Scott quotes a letter from the Chancellor of the National University of Pekin which should set at rest any doubt as to the willingness of the Chinese themselves to co-operate in this field. While Chinese ethical standards must be respected, what is needed in the opinion of the Chinese themselves is the spirit and tradition of our best public schools. Dr. Scott concludes by indicating in outline the means of attaining this object through joint membership of the Foreign Office Advisory Committee contemplated by the Bill for dealing with the Chinese Indemnity now before Parliament, and by joint committees in China itself.

IN the *Electrician* for February 6 some results are given of radio signal measurements between Great Britain and the United States made during the eclipse, which supplement the communication from Dr. W. H. Eccles on p. 260 of this issue. The experiments were carried out in Great Britain by the General Post Office, the Radio Research Board, and the International Western Electric Co. In the United States the Radio Corporation transmitted special signals from an experimental station situated at Rocky Point, Long Island. In Great Britain the Leafield and Northolt stations sent signals Similar observations were made on the day preceding and the day following the eclipse. Measurements were made both of the intensity and the apparent bearing of the signals On the day of the eclipse, there was a well-defined rise to a very sharp maximum of the signal intensity. This was followed by an equally well-defined minimum. The rise corresponded approximately to the intersection of the path of the beginning of the eclipse with the great circle passing through the transmitter and the receiver The minimum of signal intensity coincided to within one or two minutes with the intersection of the path of totality with the corresponding great circle. The radio bearings of Rocky Point were observed at Slough on January 24 and 25 and were found to be very steady in each case There was no appreciable effect that could be attributed to the eclipse Observations were also carried out at Slough on the signal intensity and bearings of Leafield, which is distant 48 miles In this case the erratic behaviour of both measured quantities was very marked. These variations are a normal daily occurrence at this period of the year and neither of the measurements seemed to be affected by the eclipse

THE Wireless Telegraphy and Signalling Bill which has been introduced in the House of Commons by the Postmaster-General, Sir William Mitchell-Thomson, is a measure of such questionable quality and scientific detriment that it is scarcely likely to pass through Parliament without substantial change The Bill is particularly objectionable from the point of view of the scientific investigator and inventor, as by it officials from the Post Office may demand, under heavy penalties, to enter any laboratory and inspect apparatus and experiments even though these do not involve any outside transmission True, this oversight of experimental work is claimed already as being in departmental regulations, but these could never be upheld The new Bill, however, would make it possible for the Postmaster-General to impose them on any experimenter or inventor. What the Bill provides for specifically is control of "the installation and working of apparatus for utilising etheric waves as they apply to the installation and working of apparatus for wireless telegraphy" Mr A A. Campbell Swinton points out in a letter in the *Times* of February 17 that a candle or any other source of radiation is producing "etheric waves" and that, as the existence of the ether itself is now questioned in certain scientific circles, much interesting litigation might be anticipated if the words now in the Bill are retained without statutory qualification. So many objections have, however, been raised to some of the clauses, as they stand at present, that the measure must meet with considerable opposition when it is under discussion in Parliament.

WE have received from Prof. G Friedel, of Strasbourg, a somewhat lengthy communication in which he maintains that his classification of Lehmann's so-called liquid crystals is valid. He calls this state of matter "mesomorphic" and so early as 1911 recognised that this embraced two distinct forms which he then called "liquides à conique" and "liquides à fils" He supposes that in the former there is a kind of periodicity in the sense that the molecules are distributed irregularly in parallel equidistant layers In the latter there is no periodicity at all, but only a general parallel orientation of the molecules. These valuable conceptions sharply differentiate the mesomorphic states from the complete periodicity of true crystals on one hand and from the complete irregularity of amorphous bodies or liquids on the other In 1922 he re-named the two states "smectique" and "nematique" (from σμῆγμα, soap, and νῆμα, thread, from the thread-like appearance of the sharp boundaries of different portions observed in polarised light under the microscope) He suggests that the English name for the former should be derived from the French rather than that the existing English word "smegmatic" (derived from the original Greek) should be used He differs strongly from McBain in holding that such bodies as soap curds do not consist of crystals but are mesomorphic, and it is for this reason that he no longer uses the designation "liquid" If, as affirmed by McBain (see photograph in NATURE of July 12, 1924, p 49), there is at least one other form of soap which may be described as a "conic anisotropic liquid," this would merely show that the same body can exist in several different "smectic" forms This, however, leaves scope for speculation as to how to explain these different varieties.

ALTHOUGH a number of investigators using X-rays have failed to obtain radiograms with any liquid crystals except for soap curds, the classification of which is in dispute, Friedel maintains that this is due to faulty technique in the case of smectic bodies such as transparent soap solutions, whereas no nematic body should give such a radiogram He announces that his son, E Friedel, has now obtained such a radiogram with ethylazoxybenzoate. Publication of this evidence will be awaited with interest. Friedel appears, however, to be mistaken in his assertion that radiograms of soap curds disclose only one set of planes, Piper (J. Phys. Soc., 1923, 35) found three spacings, namely, one wide spacing of the order of 4Å and two of the order of 4Å. R. E. Gibbs (J Chem Soc., 1924, 125, 2625), referring to the higher fatty acids, the X-ray photographs of which resemble the soap curds, remarks: "Owing to the doubt that has existed as to the nature of the fatty acids, it is of interest to note that, since this paper was written, further work has been done with stearic acid showing it to be of a true crystalline nature and demonstrating its extinction directions and brush figures. Several single crystal X-ray photographs of it have already been taken."

THREE Cantor Lectures, on January 19, 26, and February 2, were delivered at the Royal Society of Arts on "Radiological Research—A History," by Mr. V. E Pullin, Director of the Radiological Research Department, Woolwich. Mr. Pullin said that radiological research may be said to have begun in the year 1705 with the experiments by Mr. Hawksbee, F R S, on electrical discharges in vacua, followed by those of Mr William Morgan in 1785, the latter probably the first experimenter to produce X-rays. The great advance in knowledge made by scientific workers during the nineteenth century, particularly Faraday and Sir William Crookes, paved the way to the sensational discovery of X-rays by Rontgen at the end of 1895 The controversy as to the nature of the cathode stream was eventually settled by the classical work of Sir J. J Thomson in 1897 The nature of the X-rays was finally determined when, aided by Planck's theory of radiation, Prof von Laue was able to show that X-rays could be diffracted by means of crystals The accidental discovery of X-rays by Rontgen in 1895 was due to his use of fluorescent screens Much important research during the next crowded years resulted in Sir Herbert Jackson's use of a concave cathode, Mr Campbell Swinton's platinum target, and the introduction of the vacuum regulators gave us the modern gas-tubes, leading up finally to the introduction in 1913 of the Coolidge tube To-day it is possible to operate a tube on 200,000 volts and to examine castings 3 in thick Voltages up to 400,000 are already available at Woolwich, but no X-ray tube can stand up to more than 200,000 volts owing to vacuum and other difficulties These difficulties may call for a new type of tube, and research on this subject is now being carried out at Woolwich Modern research is also being directed on the problem of focussing, and design of very high tension direct current electrical machines Radiology should be the indispensable adjunct of all modern engineering practice, owing to the great saving that can be effected by detection of flaws in heavy castings, before expensive machining has been done During the previous week, with some new apparatus, designed and made at Woolwich, a mass of steel 4 in. in thickness was penetrated. This constitutes a record in penetration.

DR. J. H. JEANS, Secretary of the Royal Society, and Sir William Henry Ellis have been appointed members of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research.

SIR WILLIAM HARDY and Miss Ida Bircumshaw will deliver the Bakerian Lecture at the meeting of the Royal Society of March 19. They will take as their subject "Boundary Lubrication. Plane Surfaces and the Limitations of Amontons' Law."

THE Council of the Chemical Society has nominated Dr. Arthur W. Crossley as president, Dr. T. Slater Price as secretary, and Prof. F. G. Donnan as foreign secretary. The annual general meeting will be held on March 26 at 4 P.M., and the anniversary dinner will be held the same evening at the Hotel Victoria, Northumberland Avenue.

SIR THOMAS H. HOLLAND has been elected president, and the Rt. Hon. Viscount Cowdray of Cowdray, Sir John Cargill, Bart., Mr Alfred C. Adams, Mr. Alexander Duckham, Mr Arthur W Eastlake, and Mr. Robert Redwood have been elected vice-presidents of the Institution of Petroleum Technologists for the ensuing year.

THE International Health Board of the Rockefeller Foundation has made a grant of 1,100,000 kröne (about 62,000*l.*) to the Danish State Serum Institute at Copenhagen for the purpose of extending the building and laboratories. This is the third grant made to Denmark by the Rockefeller Foundation during the last year or two Previous grants were allocated to the Veterinary School and to Prof. Niels Bohr

THE following officers of the Royal Astronomical Society were elected at the anniversary meeting on February 13 *President*, Dr J. H Jeans, *Vice-Presidents*, Dr A. C D Crommelin, Dr J L E Dreyer, Prof A Fowler, Dr J. W. L. Glaisher; *Treasurer*, Lieut.-Col F. J M Stratton, *Secretaries*, Dr. J. Jackson, Rev. T. E R Phillips, *Foreign Secretary*, Prof H. H Turner

ON Thursday next, February 26, at 5 15, Sir Arthur Smith Woodward will deliver the first of two lectures at the Royal Institution on dinosaurs, and on Saturday, February 28, at three o'clock, Sir Ernest Rutherford will begin a course of four lectures on the counting of the atoms. The Friday Evening discourses on February 27 and March 6 will be delivered by Sir James Irvine, on sugars from the point of view of the organic chemist, and by Sir Arthur Keith, on the rate of man's evolution, respectively.

AT the annual general meeting of the Meteorological Society on January 18, the following officers were elected *President*, Mr C J P. Cave, *Vice-Presidents*, Dr. C. Chree, Mr J S Dines, Mr. L F. Richardson, Mr. Gilbert Thomson, *Treasurer*, Mr Francis Druce; *Secretaries*, Mr. Richard Corless, 21 Wimborne Gardens, W Ealing, W.13; Commander L. G. Garbett, Meteorological Office, Air Ministry, Kingsway, W C.2; Major A. J H. Maclean of Ardgour, Ardgour, Argyllshire; *Foreign Secretary*, Mr R G. K. Lempfert, 24A Trebovir Road, S.W 5, *Assistant Secretary*, Mr. A. Hampton Brown, 49 Cromwell Road, South Kensington, S.W 7.

THE discovery of a new urinary antiseptic by the Johns Hopkins School of Hygiene and Public Health is announced in the *Times* of February 12. Hexylresorcinol, as the new compound is named, is the outcome of several years' work by Dr. Leonard, of the National Research Council, in collaboration with Dr. Treat Johnson, professor of organic chemistry in Yale University. It is stated to be a potent antiseptic for the treatment of infections of the kidneys and urinary tract, long-standing infections of the kidneys clearing up under its use in 48 hours. The cures appear to be permanent, and no ill effects were observed.

THE Royal Society has now been notified that His Majesty's Treasury proposes to make provision in the Estimates for 1925–1926 for an increase of the Royal Society Publication Grant from 1000*l.* to 2500*l.* in the current year. This grant is available for helping the publications of other scientific societies as well as for assisting the separate publication of books, memoirs, etc, of a scientific nature Applications for grants for the current year will be considered by the Council of the Royal Society at its meeting early in July Applications from societies will be received by the secretaries of the Royal Society, those from individuals should be brought forward by members of Council

Two noteworthy gifts, for research and for education, are announced by the New York correspondent of the *Times* A fund of 600,000*l* has been raised for the establishment at Johns Hopkins University of a centre for ophthalmological research to be called the Wilmer Institute. The General Education Board has given half the money and the remainder has been subscribed by friends and former patients of Dr William Holland Wilmer, of Washington, who will retire from private practice to assume direction of the new centre. The other announcement is of a gift of 100,000*l.*, by Mr Cleveland H Dodge, of New York, to the fund for the Near East Colleges The institutions which benefit by the gift are the Robert College, Constantinople, the American University of Beirut, the Constantinople Women's College, and other institutions at Smyrna and Sofia The gift is sufficient to cover a fifth of the working expenses of the colleges for the next five years

A MEMORANDUM on the probable character of the weather in north-west India in January, February, and March has recently been issued by Mr. J H Field, the officiating Director-General of Observatories for the Government of India The forecast states that "the winter rainfall of north-west India together with the snowfall on the western Himalayas may be expected to be normal or in slight excess" These winter rains are brought by a series of depressions from south-west Europe and the Mediterranean The tendency for persistence in the winter affords indication for the later months to be based on the weather in December. The application of statistical methods to seasonal forecasting in India has been very definitely studied, and with considerable success In addition to the factors which have been in use for some time past, another feature which seems likely to prove of importance is the seasonal change of the upper air currents in northern India at a height of 4 miles above ground obtained from observations at Agra.

THE report of the Council of the Optical Society submitted to the annual general meeting of members on February 12 shows that the efforts of the Society to promote and advance the theory and practice of optical science are being well maintained. The steadily increasing interest that is being taken in this subject is evidenced not only by the nature and number of the papers presented to the Society, but also by the interest taken in the Society's Transactions, in which these papers are printed. By means

of special exhibits and demonstrations at recent meetings, attention has been directed to instruments and apparatus of historic interest as well as to modern developments of various optical instruments The financial position is now so satisfactory that a further extension of the Society's activities is under consideration The following officers have been appointed for the current session. *President*, Mr. T Smith, *Vice-Presidents*, Instr.-Comdr. T. Y. Baker, Prof Archibald Barr, Sir Frank Dyson; *Hon. Secretaries*, Mr F F. S Bryson, Prof A F C. Pollard, *Hon Treasurer*, Major E O. Henrici; *Hon Librarian*, Mr J H Sutcliffe, *Editor*, Dr J. S Anderson

"TAKING a Museum to School" is the heading of an article in the *Manchester City News* of February 7 It describes a scheme which has been inaugurated by the Salford Museum for the distribution to schools of portable cases containing natural history specimens, photographs of trees, types of architecture, furniture, etc The underlying principle is sound though by no means new The idea has been greatly elaborated by the American Museum of Natural History, and in 1922, 475 schools were supplied with sets Of course, in a large museum where the staff is adequate, or when there are official guide lecturers, it were better to bring the classes to the museum When such is not possible, then exhibits may, with great advantage, be sent to the school. The cases thus supplied may show birds, animals, and so on, which children would not otherwise see, and may encourage them to visit the museum itself and so extend their knowledge But the great difficulty is the "text" accompanying the cases Such exhibits placed in the hands of teachers having no special knowledge of the subject may tend to grave misconceptions, whereas a stereotyped lecture may become irksome. Children have a way of asking peculiar questions. Before receiving such cases the teachers should have a "lesson" themselves, given by the person responsible for the exhibit

ON February 26 occurs the bicentenary of the birth of Nicolas Joseph Cugnot, the French military engineer who built the first vehicle driven by a steam engine Born at Void in Lorraine in 1725, Cugnot joined the French army, served in the Low Countries, and afterwards in Paris gave lessons in military affairs In 1766 he published his "Éléments de l'art militaire ancien et moderne" and three years later a volume on fortification He appears to have made two steam vehicles, the first in 1769 and the second in 1770 The earlier was put into motion in the presence of the Duc de Choiseul, then Minister of War, and of General Gribeauval, and it carried four persons Its steaming capacity, however, was very small, and it had to stop at short intervals to allow the steam pressure to rise. The demonstration led to the construction of a second vehicle at the Paris Arsenal, and this is now preserved in the Conservatoire des Arts et Métiers. It is doubtful if this vehicle ever ran. Intended for the transport of artillery, it was designed to carry a load of about 4½ tons at a speed of 2½ miles per hour and cost 800*l*. Though designed by Cugnot it was made by Brezin. General Morin in 1851 gave an interesting account of the machine to the Paris Academy of Sciences Cugnot continued to reside in Paris until the Revolution, when he went to Belgium. Poverty appeared to have dogged his steps, but under the Consulate he was given a small pension of 1000 livres, and he returned to Paris, where he died on October 4, 1804

IN a discourse delivered before the Royal Institution on February 13 on the forces of law and order in a primitive community, Dr B Malinowski gave an account of his conclusions in regard to primitive law arrived at during his years of field-work among savages in Melanesia In his opening remarks he referred to the Imperial value of anthropological studies for the government of savage races, and said that such studies must be directed to the actual and practical problems of savage life in order to be useful. The real task of the administrator is legislation and the meting out of justice to the natives, and the most important practical subject of anthropology should be primitive jurisprudence Upon this question anthropology hitherto has often been silent and sometimes even incorrect. Nothing could be more misleading than the statement frequently made that "all societies have passed through a stage of communal ownership and communistic sexual relation" Taking Melanesia, Dr. Malinowski showed that, in spite of most illusive appearances, the ownership of property is strictly defined and there is no trace of real communism. The so-called communism is the result of the observers looking at native custom through European eyes Another legal dogma constantly used by some modern anthropologists is "The clan or kin is the unit in primitive law and not the individual" Exogamy is usually quoted as the most perfect index of the homogeneity of the clan This again is an illusion. Dr Malinowski urged that it is in this type of anthropological analysis of savage institutions that the anthropologist can join hands with the administrator in working out a practical science of administrative anthropology.

ARRANGEMENTS are in progress for the next annual meeting of the British Association, to be held in Southampton on August 26-September 2, under the presidency of Dr. Horace Lamb, formerly professor of mathematics in the University of Manchester. Presidents of the several sections have been appointed as follows: *Mathematics and Physics*, Dr. G. C. Simpson, director of the Meteorological Office; *Chemistry*, Dr. C. H. Desch, professor of metallurgy in the University of Sheffield, *Geology*, Prof. W. A. Parks, of the University of Toronto; *Zoology*, Mr. C. Tate Regan, keeper of zoology in the British Museum (Natural History); *Geography*, Mr. A. R. Hinks, secretary of the Royal Geographical Society; *Economics*, Miss Lynda Grier, principal of Lady Margaret Hall, Oxford; *Engineering*, Sir Archibald Denny, Bart.; *Anthropology*, Dr. Thomas Ashby, director of the British School at Rome; *Physiology*, Dr. A. V. Hill, professor of physiology in University College, London; *Psychology*, Dr. C. E. Spearman,

Grote professor of the philosophy of mind, University of London; *Botany*, Prof. J. Lloyd Williams, of University College, Aberystwyth; *Education*, Dr W. W. Vaughan, headmaster of Rugby; *Agriculture*, Dr. J. B. Orr, head of the Rowett Research Institute, Aberdeen. Among the principal items already set down for discussion are transport problems, to which the Sections of Economics and Engineering will devote two days, with special reference to the railway centenary of the present year; the cost of farming and the marketing of agricultural produce (Sections of Economics and Agriculture); the functional significance of size (Zoology and Physiology), the ignition of gases (Chemistry and Engineering); tidal lands (Geography and Botany); variations in gravitational force and direction (Physics and Geology), recent investigations upon vocational guidance (Psychology and Education); the distribution of animals and plants in relation to continental movements (Geology, Zoology, and Geography), the acquisition of muscular skill (Physiology and Psychology), and discussions on health in schools, the disciplinary value of subjects, the training of teachers, and the teaching of biology. Prof. Parks, of Toronto, as president of the Geological Section, succeeds the late Dr Willet G. Miller, the Ontario Government mineralogist, who was to have occupied the chair of the Section.

WITH the January number the *Illuminating Engineer* begins a new stage of its existence Formerly it was merely the official organ of the Illuminating Engineering Society; it has now been extended so as to appeal to a much wider class of reader This number is brightly written and shows that good methods of illumination are of general interest. During last year no very striking progress was made in inventing new lamps or incandescent mantles, but considerable progress was made in the methods of applying illuminants. It is considered that the time has come to enlighten the public as to what is being done. Playing games by artificial light, lighting developments at the Zoological Gardens in Regent's Park, the psychology of illumination, lighting and tobacco, inadequate lighting and defective vision, illuminated name plates for motor cars, and artistic illumination are only a few of the subjects discussed. We were specially interested in the "possibilities and limitations" of motor-car headlights. It is pointed out that the glancing beam of the headlight does not show to the driver puddles of water in the road During the floods of December, inability to locate fairly deep water ahead often proved embarrassing This shows that headlight illumination is far from perfect

IN our issue of February 14, p 242, reference was made to an article by Mr. F W Shurlock on the Rev A Bennet, F R S., in the January number of *Science Progress* Mr Shurlock writes to point out that the statement that Bennet died at Fenny Bentley is inaccurate He held the rectory of Fenny Bentley concurrently with the curacy of Wirksworth, where he lived, died, and was buried, a memorial tablet is in the church, on the south wall of the nave

AN assistant is required in the new chemical laboratory of the City Analyst for Leicester The work of the person appointed will be mainly in connexion with the analysis of food and drugs, water and sewage effluents The latest date for the receipt of applications by the Medical Officer of Health, Leicester, is Thursday, March 5.

ERRATUM.—In NATURE of February 14, p 236, column 2, line 46, for words "that is" read "at all events"

Our Astronomical Column.

THE LUNAR ECLIPSE OF LAST AUGUST.—*C.R. Acad. Sci.* of Jan. 19 contains a research on the brightness of the moon at this eclipse, made by J. Dufay and A. Conder at St. Geniez (height 3500 ft.) in a clear sky. They used the Dufay photometer, which gives results that are independent of the diameter of the body measured. The moon was compared with Mars and Jupiter, the magnitudes of which were taken as −2·6 and −1·8. In the following table D is the distance in minutes of the moon's centre from the centre of the shadow, V its visual and P its photographic magnitude, C the colour-index.

D	V	P	C	D	V	P	C
10′	−0·9m	... m	m	18′	−1·35m	+0·7m	2·05m
12	−1·0	+3·2	4·2	20	−1 65	0·0	1·65
14	−1·1	+2·3	3·4	22	−2 1	−0 7	1·4
16	−1·2	+1·4	2·6	24	−2·7	..	..

The increase of red in the centre of the shadow is very noticeable, and was also observed in the telescope, the outer portion of the umbra being greenish grey, the next zone orange-red, the centre brownish red.

The colour-index of Mars was determined as 1·37m ±0·06m. It presumably varies with the character of the markings on the disc at the time.

Comparison was made with the eclipse of Oct. 16, 1921, observed by M. Danjon. It was concluded that the moon in 1921 was four times as bright as in 1924, presumably owing to greater cloudiness in the earth's atmosphere in 1924

ASTROGRAPHIC ZONE 21° SOUTH (HYDERABAD).—The Hyderabad Observatory (Director, T P Bhaskaran) has shown most praiseworthy zeal and energy in completing not only the zone originally undertaken but also the zone −21° to −23°, which had been undertaken by two other observatories in turn, but abandoned by both of them. It was thanks to the liberality of the Nizam and his Government that this extension was possible. The present volume contains the measures of stars on the plates the centres of which are in declination 21° south. The average number of stars per plate is 491, a higher average than in previous zones; this is ascribed to improvement in the quality of the plates Plates were rejected that did not show at least twice as many stars as Schönfeld's map. In the galactic zones, some fifteen times as many stars are measured as are contained in the map, although the measurers were instructed to pass over the very faint stars in these regions.

The catalogue contains the measured diameters, with data for deducing the magnitude, and the x, y co-ordinates to 3 decimals of a réseau interval; also provisional plate constants for reducing to R.A. and decl. The plates in the present volume were exposed between Dec. 1920 and June 1923.

Research Items.

PSYCHO-ANALYSIS AND MOTHER-RIGHT.—In *Psyche* for January, Dr B. Malinowski concludes his examination of the applicability of the Freudian theory of the Œdipus complex to a society organised on a matrilineal basis. In his previous contribution to this subject (*Psyche*, April 1924) it was shown that whereas under the *patria potestas* the conflict is concerned with father and mother, in the matrilineal family of the Trobriands, it affects the sister and the mother's brother. Turning now to the question of disease and perversion, it appears that among the Trobrianders, where sexual desires are allowed a natural outlet at an early age, perversions and neurotic affections are comparatively rare, while in the Amphletts, where sexual license is repressed, they occur with frequency. The evidence of dreams, distinguishing "free dreams" from "official dreams" of a divinatory or magical character, points to repressed desire in the direction of the sister. This form of incest is regarded with such horror that at first sight it might appear never to occur, but careful investigation has revealed that it does exist. Both obscenity and myth bear this out. Abuse by attribution of mother and sister incest, though both actions are abhorrent to the Trobriand mind, in the degree of resentment it arouses indicates that there is a real temptation to break the strong taboo against the sister. In the same way, throughout the myths of the Trobrianders there runs a strong matrilineal complex; in the tales of origin, no father appears, and when a male member of the family is mentioned in such a manner as to indicate a conflict of some kind, it is the maternal uncle.

THE PROBLEM OF ARISTOTLE.—Prof. Burnet's British Academy "Master-mind" Lecture ("Aristotle," Oxford University Press, 1*s*.) is of more than usual interest, not only to classical and philosophical students but also to men of science. Aristotle's real greatness, Prof. Burnet tells us, was as a biologist. The most important formative period of his life was the middle period, the years when he was lecturing at Assos and afterwards when he removed to Mytilene in Lesbos, where he made his careful observations and studies of marine forms of life. Prof. Burnet refers to the recent important work of Prof. Werner Jaeger of Berlin ("Aristoteles, Grundlegung einer Geschichte seiner Entwicklung"). The conclusions of this book are in accord with Prof. Burnet's own independent studies of the problem, though he differs from the author on some points of minor importance. The curious problem about Aristotle is that scarcely any of the works we possess, and none of the important ones, were published in his lifetime or intended for publication, or in a form in which he would have acknowledged them or consented to their publication. Yet it seems certain that they represent his mature views in a way which his published works did not. They are his written lecture notes, and they have been preserved by a strange accident, while his own published works, by which alone he was known in the first two centuries after his death, are lost. What Prof. Burnet brings out with exceptional clearness is that the contrast between Plato and Aristotle and the latter's criticism of the former's doctrine of forms is explained by the fact that, while Plato was exclusively interested in mathematics, Aristotle's attention was directed towards biology.

TERTIARY MAN IN ENGLAND.—A review of the evidence bearing upon the question of tertiary man in Britain by Mr. J. Reid Moir, appears in vol. xxiv., No. 6 of *Natural History* (American Museum of Natural History). The vast geological age of the Kentian eoliths finds support in East Anglia. There the White Coralline Crag, which is definitely earlier than the Red Crag, was laid down in a warm period, the deposition of the Red Crag beginning with the irruption of arctic waters. The Red Crag detritus contains material of different periods due to denudation, including eoliths of Kentian type, much rolled and abraded, and later forms of which the rostro-carinate is the outstanding implement. The Red, and Norwich Crags, and their underlying detritus bed, represent the first glacial deposit in East Anglia. The Foxhall implements belong to the Crag itself and are clearly later than the detritus bed implements, as is shown in the variation in patination when, as in several cases, the former has been made out of the latter, but implements of the same kind as are found at Foxhall occur at Thorington Hall *beneath* the Crag, where man evidently lived on a surface of London clay instead of Crag. The Cromer implements are to be regarded as Early Chellean, a classification supported by the fauna. In an appended note in the same publication, Sir E. Ray Lankester questions the use of the term "quaternary" to describe the strata later than pliocene, on the ground that they are adequately described as tertiary, as there is no separation of later deposit from pliocene as there is of tertiary from secondary and secondary from primary. The term pliocene should be applied to the White Coralline Crag on the ground of its Molluscan fauna in many respects identical with that of deposits distinguished by the marine "Pliocene"; while the Red Crag should be assigned to the Pleistocene, it being recognised that the shells, bones, and teeth of cetaceans and terrestrial mammals in the Suffolk Bone Bed, which were assigned by Lyell and his followers to the Red Crag, and its sea are derived from earlier strata and are not contemporary with the Red Crag.

THE PLEISTOCENE VERTEBRATE FAUNA OF NORTH AMERICA.—The Carnegie Institution of Washington has published (October 1924) an account, by Dr. O. P. Hay, of the pleistocene vertebrate palæontology of the region west of the Mississippi, a continuation of a previous account which dealt with the regions east and north of the river. The volume deals with the discovery of various groups of mammals, each group being taken separately, and the places where species of the group have been found are detailed in order for each province. More than a quarter of the account concerns the places where Proboscidea have been found, mastodons and, in particular, *Elephas boreas*, *E. columbi*, and *E. imperator*. Other groups detailed are the Xenarthra, horses, tapirs, peccaries, camels, deer, bison, and beavers. Twenty-nine maps illustrate the positions where material has been found, and an index, which is very complete, gives reference both to the animals and their localities. The work will be very useful for reference by any one studying the Pleistocene of North America as well as for purposes of comparison with the corresponding faunas of the Old World in questions of migration and distribution.

CARBONIFEROUS ROCKS IN CENTRAL JAPAN.—A recent issue of the Scientific Reports of the Tôhoku Imperial University at Sendai (vol. viii., No. 1) contains an important paper by Ichirô Haysaka "On the fauna of the Anthracolithic Limestone of Ômimura in the western part of Echigo." The paper has had a chequered career; originally written in 1920, the MS. was destroyed in the Tokyo fire that followed the earthquake of September 1, 1923, and

the whole work has been courageously rewritten since. The locality considered lies on the northern side of the Central Island, almost due north-west of Tokyo The formations represented by the thick mass of almost vertical limestone, about 2 km in thickness, there developed probably include the Permian down to the Tournaisian The fossil fauna comprises Foraminifera (including, of course, the well-known Fusilina), corals, Brachiopoda, Bryozoa, a crinoid, and a very few mollusca. Altogether, 41 species are recorded, but only four are regarded as new, while several are indeterminate. Representative specimens receive illustration on six plates of that standard of excellence which we have come to associate with Japanese productions, whilst there is, further, a map of the district giving the geological details. The author points out that the Lower Carboniferous formation of marine origin is almost absent from continental Eastern Asia—China, Korea and Manchuria—although it seems to be recognised in the province of Yun-nan, and has been reported from Central Asia What was the relation between the Lower Carboniferous waters of Central Asia and of the eastern border land is, as he remarks, a very interesting question

CHROMOSOMES OF WHEAT HYBRIDS.—Mr A E Watkins (*Journ. of Genetics*, vol 14, No 2) has made an important investigation of the chromosome behaviour in certain hybrid wheats. From earlier work of Sakamura, Kihara, Sax and others, the wheats are known to fall into three groups having chromosome numbers which are different multiples of 7 An intensive study was made of the chromosome distribution in the pollen mother cells of F_2 and F_3 plants derived from crossing Rivet wheat (*Triticum turgidum* var $2n = 28$) with varieties of *T vulgare* ($2n = 42$) The F_1 plants have 35 chromosomes, and two plants from later generations were especially studied, one having 31 chromosomes ($14 \times 2 + 3$) and the other 38 ($= 17 \times 2 + 4$). The history of the unpaired chromosomes is followed and the mathematical probability of the various types of pollen grains which will be formed, based on random distribution, is worked out From these observations and those of Kihara, it is found that plants with less than 35 chromosomes never have more than 14 bivalents, and in plants with more than 35 chromosomes the sum of the number of bivalents and univalents is always 21. One tentative explanation offered is that in these hybrid plants only pollen grains with 14 or 21 chromosomes function. There is evidence from other plants that the unpaired chromosomes are frequently or usually lost

THE CARBON BLACK INDUSTRY.—A few years ago the carbon black industry of the United States was one of the minor "side-lines" of natural gas production, and some peculiar state legislation very nearly killed it altogether, especially in Louisiana A new demand for this commodity, however, has arisen and has influenced operations to such an extent that the output for 1923 (during which year 138,262,648 pounds were produced) represented an increase of 104 per cent. over that obtained in the previous year. The cause of this remarkable spurt is the demand by the rubber companies manufacturing pneumatic tyres for motor vehicles; carbon black is thus employed with considerable advantage both to manufacturer and to user. Mr. G. B. Richardson, in Mineral Resources of the United States, 1923, part 2, gives figures to show that the average yield per thousand cubic feet of gas is 1·3 pounds of carbon black, and the estimated quantity of gas used for the purpose in 1923 was 109,096,000 thousand cubic feet. Louisiana, the most important producer in America, was responsible for practically 75 per cent. of the total amount, West Virginia and Kentucky yielding the next largest outputs It is interesting to note, however, that during the latter part of 1923 a state of over-production of this substance was reached, and as this corresponds with a period of great activity in the pneumatic tyre industry, we may gauge to some extent the possible economic limit to the manufacture of carbon black for this purpose and to the expansion of the industry The price of carbon black at the plant averages about 8 5 cents per pound

PHYSICAL CONSTANTS OF ICE.—The specific heats and latent heats of fusion of ice have recently been determined by O Maass and L J. Waldbauer (J Amer Chem. Soc, Jan 1925). The method used enabled measurements to be carried out at low temperatures. The specific heat of ice, determined at ten-degree intervals from $-180°$ to $0°$, was found to be accurately represented by the equation $c = 0.485 + 0.000914t - 0.00000546t^2$, the latent heat of fusion is 79·42 cal. per gram The specific and latent heats of some organic liquids were also determined, the results indicate that atomic heat is a highly constitutive property when the specific heat of a compound varies greatly with the temperature

THE SUN AND ATMOSPHERIC ELECTRICITY.—In the March and December 1924 issues of *Terrestrial Magnetism and Atmospheric Electricity*, Dr Louis A. Bauer has collected together and discussed the observations on atmospheric electricity made on undisturbed days during the past seven sunspot periods. He concludes that the atmospheric potential gradient and its daily and seasonal variations, and the air-earth electric current, are influenced by sunspots. As a rule the gradient and the ranges of its daily and seasonal variations are increased about 30 per cent by the change from minimum to maximum sunspot frequency, but there have been periods in which they have decreased, and in these periods terrestrial magnetic activity has also decreased The gradient and the ranges of its variation are greatest near the equinoxes and least near the solstices

GUN WIRE.—The system of wire-winding of guns first proposed in 1855 was introduced about 1890 with the object of effecting a distribution of the firing stresses in a more uniform way than could be attained by shrinkage alone The steels employed usually contained from 0·6 to 0 7 per cent of carbon, and British gun wire is in the form of a tape or ribbon 0·25 in wide by 0·06-0 04 in thick with rounded edges The steel is severely cold-worked, and exhibits a comparatively low elastic limit in spite of its high tensile strength, but it has long been recognised that this condition of imperfect elasticity in the wire under tension can be removed by a low temperature heat treatment We have received from the Research Department, Woolwich, R D. Report No 60 entitled "Gun Wire The Effect of Low Temperature Heat Treatment on the Properties of Cold-Strained Steel and Its Behaviour under Stress at Raised Temperatures" The work described was undertaken with the object of providing a material which would maintain a condition of constant stress with constant strain at a given temperature whatever the variation (within certain limits) of strain and temperature to which it was subjected in use The author, Dr. Greaves, as a result of his investigations, concludes that if it is required to ensure a constant tension in the wire at atmospheric temperature, in

spite of considerable variation in the temperatures to which it may be subjected in use, the wire must be heat-treated at a temperature not below 200° C The lower limit of the temperature of preliminary treatment (in excess of 200° C) is fixed by the fact that it must be above any temperature to which the wire is likely to be subjected in use On the other hand, the upper limit of temperature of treatment is governed by the tension which is to be maintained The higher the tension the less must the temperature of the treatment exceed 200° C. The report contains data from which the relation between stress, temperature, and preliminary treatment of the wire can be determined.

A VECTOR-TROLLEY APPARATUS.—Anything that makes the principles of mechanics more obvious to the student is sure of a hearty welcome from all teachers of the subject in schools and at universities. Considerable interest, therefore, attaches to the "Vector-trolley" apparatus designed by Mr E. J Atkinson, of the Harrow County School, and exhibited recently at the annual meeting of the Mathematical Association, and at the Royal Institution. The method is based upon the principle of the well-known problem in mechanics, where two masses, one

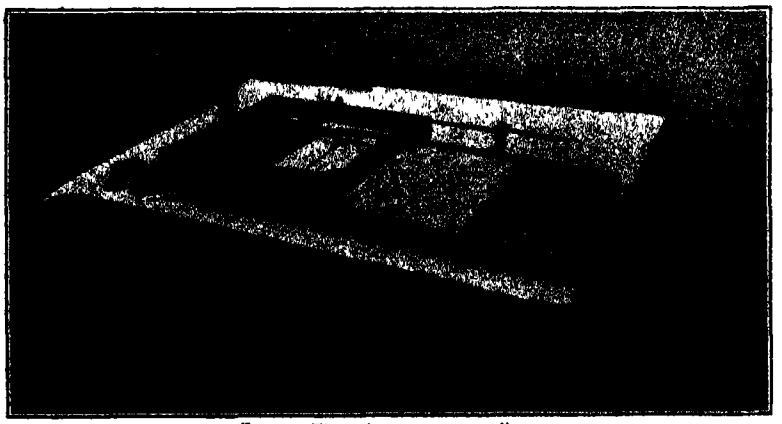

FIG. 1.—The Atkinson vector-trolley

moving on a horizontal table and the other falling vertically, are joined by a string passing over a fixed pulley. The motion is one of uniform acceleration, even if friction and the mass of the pulley are taken into account. If in this way motion is given to the mass on the table, and the hanging mass is disconnected from it, then, assuming smooth running, the mass on the table can be taken to move with constant speed for some considerable time The application of this principle by Mr Atkinson is made clear by means of the accompanying illustration (Fig 1), from which it is seen that two such accelerated or uniform motions in different directions are communicated to a registering instrument simultaneously. The angle between the two motions can be adjusted at will. Propositions like the parallelogram of velocities and of accelerations, the relationship $P = mf$, parabolic motion of the projectile, the theory of relative motion, can all be illustrated simply and convincingly. Mr Atkinson's method is very straightforward The mechanism is easily understood, and both the teacher and the student should find the use of such a mechanism of considerable value The apparatus is being manufactured by Messrs. Cussons, Ltd., of Manchester.

FORGING TEMPERATURE OF STEELS.—It is well known that, in the case of steel, forging is most effective at a certain favourable temperature which is neither too high nor too low. This is called the forging temperature. As yet no method has been discovered for measuring the forgeability of a metal. Prof. Kotaro Honda has addressed himself to this problem, and in the eighty-first report from the Research Institute for Iron and Steel and other Metals, Sendai, entitled "On the Forging Temperatures of Steels," he concludes that forgeability can be adequately measured by the elongation obtained in a testing machine. He gives reasons for considering that the mechanism of the elongation due to longitudinal tension and lateral compression must be the same, and finds that, in the case of carbon steels, the elongation temperature curve has generally two maxima and two minima. The temperatures of the maxima are at 760° and 1200° C., this latter being the temperature most favourable for forging. The temperatures of the minima are at about 900° and 300°. Hence in the process of forging low carbon steels, every precaution must be taken against a fall of temperature to 900°, where the elongation is at a minimum. In the case of medium carbon steels this minimum is inconspicuous, so that the cooling of the specimen is not so critical The investigation of a high speed tool steel containing 18 per cent of tungsten showed that the elongation temperature curve has maxima at 800° and 1100° and a minimum at 950° The maximum at 1100° is very sharp, and hence in high speed tool steels the temperature range favourable to forging is very limited.

ACTIVITY NUMBERS OF HYDROCHLORIC ACID.—The activity coefficients and transport numbers of hydrochloric acid solutions in ethyl alcohol are described in two papers by H. S Harned and M E. Fleysher, published in the Journal of the American Chemical Society for January 1925. The activity coefficient and activity of the acid are about one hundred times greater in alcoholic than in aqueous solutions. The cation transport number, determined by measuring the E.M.F. of the concentration cell $Ag/AgCl/HCl(c_1)/HCl(c_2)/AgCl/Ag$, was found to be 0·654 for 0·1N, and 0·610 for N solutions. These figures are in agreement with the results of Lapworth and Partington (1911). Measurements were also carried out in aqueous alcoholic solutions of the acid.

MICROSCOPE LAMPS.—Several novel and useful types of microscope lamps and illuminating apparatus, suitable for routine work, for micro-projection, and for dark ground and critical illumination, are described in a catalogue recently issued by Messrs. Ogilvy and Co. from their new address at 20 Mortimer Street, London, W.1. Included amongst these is the Hartridge-Williams axial illuminator. This consists of an electric lamp of suitable design enclosed in a ventilated chamber, which can be fitted to any pattern of microscope. The illuminator when fitted forms an integral part of the microscope, occupying the usual place of the mirror. By its use, errors due to polarisation or double reflection from a mirror are avoided and a light source, invariable in position, shape and character, is obtained. No external lamp or bull's eye is required, and adjustments once made are not affected by inclining the microscope or moving it about. The illuminator is fitted with an iris diaphragm which limits the area of light on the specimen to the field of the eyepiece.

Chemistry in India.

DR. M. O. FORSTER, in his address to the twelfth Indian Science Congress, has preached a sermon which is not likely to be forgotten by those who were privileged to hear it or by those who have had an opportunity of reading it. Phrased in the happy manner which came to many as a revelation on the occasion of his address to Section B of the British Association at Edinburgh, it deals with numerous fundamental and intimate questions which are exercising the minds of many thoughtful men and women at the present time. Probably no one can do this kind of thing quite so well as Dr Forster, for he enhances his constitutional optimism by a flow of language which overwhelms the pessimist and carries the reader from the start to the finish along a smooth stream of pleasing rhetoric, past a countryside replete with all that is beautiful and satisfying, only dallying here and there to point out to the traveller some piece of Nature's handiwork more entrancing than the rest, or pausing to express a feeling of admiration for the manner in which scientific man has acquitted himself It is only afterwards that the reader, whose mind, after his journey, will be in a pleasant condition of altruistic confusion, will wonder what it is all about If he is an incorrigible pessimist, and wishes to retain his sanity, he will be well advised to let the first impression stand and not to examine more closely into the nature of the raw material from which Dr. Forster has woven his fascinating fabric. If, like most of us, he is a man of the world without any unhealthy bias towards extreme optimism or extreme pessimism, but, taking things much as he finds them, bestows neither premature praise nor expresses hasty condemnation, he will find much with which he can agree and a great deal to inspire thought and contemplation.

To Dr. Forster's audience the address should be of inestimable value, for India needs scientific stimulation and inspiration far more than any other country of her importance in the world Her immense natural resources and the mental calibre of her races ought to ensure her a foremost place, both scientifically and commercially, among the nations, yet she remains chained and fettered, and probably only one in a million of her inhabitants will be in a position to take to heart the message Dr. Forster sends them Nevertheless, conditions are changing for the better, and the past twenty years have marked a notable advance in the scientific status of the Indian Empire.

The far-sighted vision of an exceptional man led to the founding of the Indian Institute of Science at Bangalore, but it was not until eleven years after the inception of the scheme that all difficulties were removed and the vesting order was signed. Meanwhile, the first director, Dr. M. W. Travers, had been appointed and had drawn up the necessary plans for the organisation and equipment of the new Institute. It is undoubtedly due to the devotion and, indeed, self-sacrifice of Dr. Travers that the scheme assumed definite shape, and that the buildings and laboratories were ready to receive the first students in July 1911. Slight changes in the original organisation were afterwards made, and at the present time there are three chief departments, namely, those of electrical technology, general and organic chemistry, and biochemistry, there is, moreover, a large central building in which the offices and library are housed, the excellence of the latter being due to the organising ability of Mr C. F H Tacchella After the retirement of Dr. Travers in 1914, the post of director was held by Sir Alfred Bourne until 1919 when, after Dr. Alfred Hay had acted as officiating director for two years, the present holder of the office, Dr M O. Forster, was appointed.

It was probably inevitable that, during its earlier years, the Institute should have devoted itself to many *ad hoc* problems arising out of the then existing conditions of Indian manufactures The intention of the founder had been to establish a post-graduate university institution having for its particular object the promotion of advanced study and original research, with special regard to the educational and economic interests of India, but, at that time, advanced education in India was not in a condition to supply a sufficient number of properly trained post-graduate students, and, in those early days, it must have been exceedingly difficult to find the right men to carry out the fundamental research upon which to base the many important industries of the country. Still, in the efficient hands of Dr Sudborough, Dr. Fowler, Dr. Watson, and Dr. Hay, much was done, and the early record of the Institute bears witness to the fact that, despite the obvious difficulties, the research work accomplished supplied material for the improvement of many industries which had hitherto been built on the rule-of-thumb and traditional methods so characteristic of Indian manufacturing procedure as a whole.

The appendix to the fifteenth annual report of the Council of the Institute, dated 1924, is now to hand, and it is evident, from the comprehensive list of investigations which the report shows are being carried out by the three departments already mentioned, that important research work of a fundamental character is being pursued. The lists are indeed pleasing to read and will stimulate Indian graduates to enter the Institute in order to obtain that training in research methods which not only broadens the outlook, but, without which, it is useless for any chemist to hope to achieve real success in industrial work. For knowledge derived from lectures and books cannot supply the vision, the independence of thought, and the honesty of purpose which are essential to the development of the scientific soul, and Indians would do well to learn the lesson some of their confrères in the west find difficult to assimilate, which is embodied in the address given by Dr. Forster at Benares.

JOCELYN THORPE.

Local Natural History in Great Britain.[1]

LOCAL scientific societies have their distinct and special place, with its incumbent responsibilities in the scientific life of the country, and it is well that this important fact should not be overlooked, particularly by the societies themselves. These, it is to be feared, do not always appreciate their obligations to organise and carry through schemes of scientific work which obviously come within their province. Intensive investigations, both systematic and ecological, of the fauna and flora of the country are problems pre-eminently suited to the activities of local societies. In fact, it will be only by the active co-operation and organisation of such societies that

[1] The North Staffordshire Field Club: Transactions and Annual Report, 1923–24.
The South-Eastern Naturalist, being the Proceedings and Transactions of the South-Eastern Union of Scientific Societies for 1924.
The Liverpool Geological Society: Proceedings, vol. 14. Part I., session the sixty-fifth, 1923–24.

it will ultimately be possible to complete our knowledge of these matters.

It is, therefore, with particular pleasure that we direct attention to Mr. L. A. Carr's paper on "The Ichneumonidæ of the Lichfield District, Staffordshire," in the first of the three volumes of annual reports and transactions here noticed, as an admirable example of the kind of work which can and should be attempted by all local societies.

In the course of only eight years' intensive and constant work, Mr. Carr has collected and identified no fewer than 1255 species of this difficult and much neglected group of insects. We do not overlook the work of Mr. Claude Morley and other isolated workers in this field, but obviously the few experts available in Great Britain cannot be expected to cover the whole ground unaided, even if the exigencies of time and expenses for travel could be met. Responsible local workers, like Mr. Carr, are required for all branches of zoology and botany, who, by their own enthusiasm, or aided by the organisation of their local societies, will make themselves responsible for one small part of the field of natural history in the immediate neighbourhood in which they live, and by care, patience, and steady work gradually get together the necessary data from which a true and accurate knowledge of the British flora and fauna can be obtained. Mr. Carr's paper is abundant evidence of the need for such work. No fewer than 335 species in his list are recorded from the British Isles for the first time, and sixteen of the species are new to science. Mr. Carr has had his identifications confirmed and his material examined not only by Mr. Morley but also by Profs. Habermehl and Schmiedeknecht and other leading authorities on the continent. His list is thus authoritative and forms a very valuable contribution to British zoology. Research of this kind is being done widely throughout Great Britain, but we would especially plead for more co-ordination and co-operation in such work by the local societies and urge upon them the example of Mr. Carr's work.

The smaller and less wealthy local societies have received much encouragement and stimulation by their affiliation to form larger bodies, of which the Yorkshire Naturalists' Union is so splendid an example. This and other similar bodies, like the recently formed Union of South-Western Societies, the South-Eastern Union of Scientific Societies, the Lancashire and Cheshire Fauna Committee, and the Faunal Survey of Glamorgan, are attempting to systematise research among affiliated societies and to carry it out on the broad lines suggested above. We should like to see this principle of larger unions extended to embrace the whole country, so that with the local societies affiliated to their proper union, and the unions in turn affiliated to one or other of the scientific societies in London, or, as now, to the British Association, a complete organisation would be brought into being for the thorough co-ordination of the work of local societies.

The unions perform another and perhaps equally important function in bringing the results of scientific research before the general public of the areas they represent, by holding annual congresses at which leading men of science deliver addresses on the special subjects of their own work. The annual volume issued by the South-Eastern Union of Scientific Societies for 1924 gives an account of its annual congress held at Guildford last year, at which Sir Richard Gregory presided and delivered an inspiring address on "Science in Civilisation," in which he sought to revive the belief in the power of science to promote spiritual and material progress and to plead for the fuller recognition of what it has done for the benefit of man. Among the sectional addresses delivered at this congress may be mentioned "Evolution and Eugenics," by Dr. A. F. Tredgold, "The Educational Value of Regional Survey," by Sir F. G. Ogilvie, "Some Remarks on Adaptation," by Dr. A. B. Rendle, and "Modes of Protection in the Pupal Stages of Butterflies and Moths," by Prof. E. B. Poulton.

It is impossible to estimate the value or to overemphasise the importance of the work which the larger unions are doing by this means. A direct link is established between the local societies and scientific workers of the first rank, and the stimulus which the former receive as the result of this contact must largely influence their members and encourage them in the work they are seeking to do.

From the same report we learn of another branch of work which the South-Eastern Union is endeavouring to do, namely, the compilation of a card catalogue of all faunal records for the area, with full notes of all localities. Such bibliographical work is important and useful, and we are glad that the Union, as well as other similar bodies, is alive to the necessity of doing it.

An admirable example of the work done by a local society in one special field is provided by the first part of vol. 14 of the Proceedings of the Liverpool Geological Society here noticed. The seven papers which go to make up this volume include the results of original research by members of the Society, and four of them deal exclusively with aspects of local geology, to the elucidation of which they form a most valuable contribution.

The three publications under notice give ample evidence of the importance and real value of the work of the societies publishing them. They are representative of the work carried on by kindred societies all over Great Britain, and they provide a splendid example to others of the results which can be obtained by organised research, and the scope of the research which local societies can profitably and creditably pursue.

Artificial Incubation.

TWO articles on "The Scientific Principles of Artificial Incubation," by Mr. Llewelyn B. Atkinson, which are of interest to biologists and physicists and of considerable importance to the poultry farmer, have appeared in the Journal of the Royal Society of Arts, November 28 and December 5, 1924.

In Egypt, China and Malay, natural methods of hatching have been replaced successfully by artificial for thousands of years, but among Western peoples the problem of artificial incubation was only solved so late as 1882, when Hearson produced his incubator with a capsule temperature regulator. The Chinese plan is described in "Farmers of Forty Centuries" by Prof. King of the University of Wisconsin, and it is claimed that with this apparently crude method 95 to 98 per cent. of the fertile eggs are hatched. By the Egyptian method described by Capt. Cadman at the Harper Adams Poultry Conference, 1923, 85 to 90 per cent. of the fertile eggs are hatched. Using modern European and American incubators, there is an all-round hatching efficiency not greatly exceeding 55 per cent. of the fertile eggs, though there are plenty of hatches up to 85 to 90 per cent. It is accepted that incubator-hatched chicks compare very unfavourably with those reared by the mother hen, and that the troubles attendant on artificial incubation do not end with the hatching.

Mr. Atkinson sets himself the task of finding why it is

that with far more delicate arrangements than a hen provides, the results obtained by the use of the incubator do not always equal those given by the sitting hen. He concludes that an incubator which will do all that the best hen does and do it regularly and with certainty, is a perfectly realisable instrument. He gives very full details of the physical and biological factors involved in incubation, drawn largely from the results of his own experimentation, and the conditions underneath the sitting hen are compared in detail with those that exist within the various types of standard incubators. The outstanding conclusions at which he arrives are that practically every type of incubator has the air too dry, that the average temperature of the eggs in an incubator is much more regular than in a hen's nest; and that, whereas in modern incubators the whole of the egg is nearly of the same temperature, the temperature of the top being only slightly different from that of the bottom, in the hen's nest the difference between the temperature of the hen's body in contact with the egg and the temperature of the lower surface of the egg is between 14° and 20° F.

From these observations the author concludes that the secret of successful incubation lies in keeping the upper surface of the egg hot and the lower surface relatively cool. This object is attained by covering the upper surface of the eggs with a very thin sheet of india-rubber. The use of this in a hot water incubator, in which the heat reaches the eggs by radiation, is rendered extremely difficult by the fact that the temperature of the tank has to be raised to a most inconvenient degree. In the case of the hot air type of incubator, however, it is quite simple to get a difference of 14° F. between the top and the bottom of the egg by the use of this rubber sheet. It was found also that with this method rapid evaporation of moisture was prevented and that, in fact, the amounts of moisture and carbonic acid around the eggs were nearly those present in a hen's nest. Using this method, an incubator which previously had rarely given more than 55 per cent. hatched more than 95 per cent. of the fertile eggs. It is to be noted that the application of heat to the eggs is by direct contact and conduction instead of by radiation or convection. Every egg becomes its own regulator, controlling the passage of the heat from the upper surface of the egg to the cooler under surface. Mr. Atkinson states also that the chicks emerging from an incubator provided with this rubber sheet are far more viable.

The Blue Whale.

MR. GERRIT S. MILLER'S paper, "Some hitherto unpublished photographs and measurements of the Blue Whale" (Proc. U.S. Nat. Mus., Vol. 66, pp. 1-4, Pls. i.-ix.) is a welcome contribution to the literature of Cetacea. In spite of its predominating importance to modern whalers, the blue whale (*Balænoptera musculus*) is still imperfectly known, particularly with regard to cranial characters. Mr. Miller publishes specially good figures of the skull, the rostrum of which has not suffered from the warping which commonly occurs on drying. He informs us that the specimen (Washington Museum) was an adult male, 75 feet long, captured off Newfoundland in 1903; but it may be remarked that the free condition of the distal epiphyses of the radius and ulna figured in Pl. viii. is evidence that the animal had not completely passed the adolescent stage of Flower, and that in any case 75 feet is a small measurement for a really adult blue whale. The digits shown in the same figure appear to be too straight, and the hand is probably a reconstruction of a disarticulated flipper, as indicated by the fact that the numbers of the phalanges are low as compared with other records.

Mr. Miller makes no comparisons, and his facts must speak for themselves. With regard to the skull, the rostrum deserves special notice, its sides being parallel in its posterior half, then converging in a gentle curve to the tip;—in striking contrast with the triangular, straight-sided rostrum of the fin whale (*B. physalus*). The premaxillæ are noticeably parallel behind, instead of being arched outwards. The postero-internal processes of the maxillæ are long, the orbital plates of the frontals diminish greatly in diameter in passing outwards, and the nasals are stout and broad. The palatines have parallel sides, and in the side view the straight outer edge of the maxilla and the outline of the vertex are other features in which this skull differs from that of a fin whale. Excellent figures are given of the atlas, axis, sternum, pelvic bones and scapula, the last showing the restored cartilaginous parts. As bearing on the great variability of the bones in the larger Cetacea it may be noticed that the sternum differs conspicuously from those figured by True in 1904, as well as from that of the Longniddry whale described by Turner. The long series of measurements of bones will be valuable as material for comparison with southern blue whales, the identity or otherwise of which with the northern species it will be the special object of the *Discovery* expedition to investigate.

S. F. H.

University and Educational Intelligence

BRISTOL.—A research assistantship is open at the Merchant Venturers' Technical College to candidates with an honours degree in engineering. Applications should be made to Prof. A. Robertson at the College.

CAMBRIDGE.—Mr. Arthur Berry has been elected vice-provost of King's College. A new post of assistant director of magnetic research at the Cavendish Laboratory, without stipend from the University, has been established for Dr. P. Kapitza, Trinity College.

By a recent vote of the Senate, the University is to ask the Commissioners to remove from the statutes the paragraph under which certain holders of official positions, such as bishops, heads of house, and privy councillors, can at present be granted degrees *honoris causa* in virtue of the positions that they occupy. University and college teachers and officers are still to be eligible for the degree of Master of Arts, and the University retains its powers to grant honorary degrees to members of the Royal Family, to British subjects who are of conspicuous merit or have done good service to the State or to the University, and to foreigners of distinction.

Dr. Haddon is resigning from the readership in ethnology.

The vice-chancellor, Dr. Fitzpatrick, president of Queen's College, Dr. Giles, master of Emmanuel College; Mr. F. J. M. Stratton, Gonville and Caius College; and Mr. R. E. Priestly, Clare College, have been appointed delegates at the coming conference of the universities of Great Britain and Ireland.

Sir R. H. Biffen, St. Catharine's College, Mr. R. Adie, Trinity College, Mr. F. L. Engledow and Mr. C. W. B. Wright, St. John's College, have been appointed to represent the scientific workers on the Station Committee of the Horticultural Research Station, while Messrs. W. P. Seabrook, A. G. Daniels, and A. T. Paskett represent the fruit and vegetable growers.

Notice has been given that an election will be made next July to the Charles Abercrombie Smith Studentship of 150*l.* a year at Peterhouse. Every candidate must be or must become a research student, proceeding to the degree of Ph.D. The studentship is normally for two years and may be renewed in exceptional circumstances for a third year.

DURHAM.—The seventh Earl Grey memorial lecture will be delivered at Armstrong College on Thursday, March 5, at 7 30, by Dr. F. W. Aston, on "The Structural Units of the Material Universe"

Applications are invited for the professorship in botany at Armstrong College The latest date for the receipt of applications (in each case ten copies) is May 15 They should be sent to the Registrar of the College, Newcastle-upon-Tyne

LONDON —The two following courses of free public lectures at the Royal School of Mines are announced "Chemical Combination in Metallic Alloys and its Nature," by Prof C A Edwards, at 5 30, on March 3, 4, 10, and 11, and "Tubbing Deep Shafts" and "Subsidence," by Prof L Denoël, at 5.15, on March 16, 17, 18, and 19 Free public lectures will be delivered at University College as follows: on March 4, 11, and 18, "Nutrition of the Young Animal," by Prof. T. B. Wood, and on March 9 and 11, "Vital Statistics," by Prof H Westergaard. The lecture hour in each case will be 5 30.

MANCHESTER —Messrs. Brunner, Mond and Co, Ltd, have continued their grants in aid of research in the Departments of Physics and Chemistry.

The Council has adopted regulations for the award of the Philip Buckle Research Scholarship in agricultural zoology This scholarship has been endowed in memory of the late Philip Buckle by his brothers and sisters

Mr J C. Oakden has been appointed assistant lecturer in mechanical engineering in the Faculty of Technology.

THE City of Cardiff Education Committee will shortly appoint a head of the department of physics of the Cardiff Technical College Applicants for the post should send 20 copies of their applications and testimonials on or before Saturday, February 28, to the Principal of the College

APPLICATIONS are invited by the Manchester Municipal College of Technology for the position in the college of lecturer in the chemistry of fermentation processes Particulars of the appointment and a form of application may be obtained from the Registrar The latest date for the return of the completed form is March 14.

THE Commonwealth Fund, 1 East 57th Street, New York, was founded in 1918 by Mrs. Stephen V. Harkness "to do something for the welfare of mankind" and is a philanthropic institution which has already made some noteworthy gifts. It is now announced that twenty fellowships a year in American universities, each of the value of about 600*l.*, have been established for British graduates by the Fund. The fellowships will be tenable for two years, and election will be by a committee of award consisting of Sir Walter Robert Buchanan-Riddell, Bt., Principal of Hertford College, Oxford (chairman), Sir Hugh Kerr Anderson, Master of Gonville and Caius College, Cambridge; Sir James Colquhoun Irvine, Principal of the University of St. Andrews; Sir Theodore Morison, Vice-Chancellor of the University of Durham; and Prof. T. Percy Nunn, Principal of the London Day Training College. The Prince of Wales has consented to become honorary chairman of the committee. The general object of the fellowships is to promote international goodwill and generally to foster unity of thought and purpose in the United States and Great Britain The awards will therefore be made on the basis of character, ability for leadership, health and general fitness, and on the nomination of recognised universities of Great Britain and Ireland.

MR. H SIMPSON GEE, of Knighton Frith, Leicester, who died last July, bequeathed to University College, Leicester, of which he was honorary treasurer, 20,000*l.* free of all duties, to found "The Simpson Gee Endowment Fund" Under the provisions of the will the executors could have deferred payment of the legacy for three years, but they generously offered to discharge the legacy forthwith and give the College the option of taking over certain specified securities of a full trustee character at the "market price" of the day. This offer the College Council gratefully accepted, and as a consequence trustee stocks of this value have been transferred, by which the endowment income of the College has been augmented by 980*l* per annum. Other gifts recently received are:—2000*l* from Sir Jonathan North, chairman of the College Council (by which his donation to the General Endowment Fund has been brought up to 5000*l.*), and 3000*l.* from Messrs Stead and Simpson, Ltd, to the fund for endowing lectureships in chemistry and physics Leicester University College, although brought into existence in 1921 during the post-War economic depression, has, nevertheless, in addition to the finest site in Leicester, on the top of the city, and large and beautiful buildings and college gardens, valued at 150,000*l*, obtained an invested endowment fund which has just completed its first 100,000*l*. In addition, it receives an annual grant from the city of Leicester. By the beginning of next academic year, it will have teachers in all the main subjects of university study, unusually adequate equipment in laboratories, and a library of 9000 volumes

THE annual distribution of prizes was held at the Sir John Cass Technical Institute, Aldgate, London, E.C 3, on Tuesday, February 10, when the prizes and certificates were distributed by Mr S. O. Nevile, past-president of the Institute of Brewing. The chairman of the governing body, the Rev. J F. Marr, in giving a summary of the work of the Institute, stated that although the courses of study at the Institute are principally conducted in the evenings, no fewer than 36 students were successful at the examinations of the University of London during the past session, two of whom obtained the degree of Ph D, and three the degree of M.Sc., by research. In addressing the students, Mr. Nevile stated that institutes such as the Sir John Cass Technical Institute supply two urgent needs of modern industrialism: they offer opportunities for advanced scientific education and training in research, and they enable those engaged in the minor ranks of industry to obtain a knowledge of the principles which underlie their daily work and a broader conception of their industry as a whole. The technology of brewing comprises—first, the production of the raw materials; secondly, the treatment of those raw materials to provide a satisfactory extract; and thirdly, the process of fermentation itself. Pasteur must be regarded as the father of the modern conception of fermentation as applied to the brewing and wine industries. Our knowledge of hops and barley is still very incomplete, and the research scheme of the Institute of Brewing is largely concentrated on these two main fundamental issues.

Early Science at Oxford.

February 22, 1683–4.—A letter from Mr Aston dated Feb. 14 was read, which gave an account of an experiment lately shewn before ye Royal Society by Mr. Paget, viz ye south pole of ye inclinatory needle followed ye flame of a quarter of a sheet of paper, 5 degrees, ye side of ye box being very little hot, ye inclinatory needle was hung in ye plane of ye meridian; ye North pole shunned ye flame.—With regard to a fountain in Poland, that is said to follow ye motion of ye Moon, is cold to ye touch, and yet easily inflammable, Dr Plot informs us, that there is a spring in Lancashire, which, though cold, takes fire, and will harden eggs

Concerning ye Lough-neagh stone, it was ordered, that ye Gentlemen of ye Society of Dublin should be desired, that they would be pleased to impart their thoughts concerning it, ye manner of its being made such, and of what materials it may be made

1686–7.—Mr Halley sent accounts (1) of Mr. Hooke's hypothesis concerning ye changes which seem to have happened in ye surface of ye Earth, from ye shells in beds found petrified in ye Alps, and other hills far from, and above ye sea, and again sea sand and shells, found at great depths underground. (2) Of an experiment of flint and steel in vacuo; which was that there were no sparks visible from ye collision, though they were very vivid in ye same receiver when ye air was admitted (3) Of a very strange effect of lightning from France, viz. that something in it pierced through a piece of glass, making some holes about ye bignesse of pistol bullets, and melting ye edges of ye glass making it smooth like ye edges of a cup. (4) That ye French in Canada have found a whole mountain of lead ore, which lies bare, so that there is no need of mining.

Whereas Mr Hooke thinks that there are not extant any authentic records of ye latitudes of places sufficiently to evince ye fixation of ye Poles, Dr. Bernard observes that ye latitude of Marseilles, taken by Pythias, in ye time of Alexander ye Great, appears to be ye same as 'tis now, and that in ye latter end of Julius Ffirmicus, is an observation of ye latitude of Oxford, taken about a hundred years since.

Mr. Lhwyd communicated ye following curiosities, sent out of ye Isle of Anglesey together with a collection of sea plants and shells:—Eggs of Skate and Dog-fish, *Favus marinus Sibbaldi*, and a broad leaved *Fucus* which had a facing of fine silk in appearance, and was all over garnished with small filaments standing upright, about an eighth of an inch long; much resembling ye stamina of flowers This surface was easily scraped off, and was supposed to adhere to this plant after ye same nature that mosses, lichens, fungi, and such other vegetables adhere to stones, trees, bones, horns, etc.

February 23, 1685–6.—A discourse concerning sounds and echoes, drawn up by Mr. Walker, was by him communicated and read.—Dr. Plot communicated some shells, *Buccina*, in which ye spirals turn to ye left

February 24, 1684–5.—A Horn was communicated by Dr. Plot, said to be a horn, which grew behind ye head of a woman, who was shewn in London about fourteen years since, and is reported to have shed her horn once in three years. This was sent by Mr. Ashmole to be laid up in his Repository.

A letter from Dr. Howman, dated Norwich Jan. 27, gave an account of a hydrophobia in an alderman of Norwich, caused by ye bite of a mad fox. Mr. Walker affirmed, that about fifteen years since a person died mad in Cheshire, having been bitten by a mad cat, which received its madness from ye bite of a mad dog.

Societies and Academies.

LONDON.

Royal Society, February 12.—H. Muir **Evans** A contribution to the anatomy and physiology of the air-bladder and Weberian ossicles in Cyprinidæ In Cyprinidæ the air-bladder is constricted, so as to form an anterior and posterior chamber connected by a short duct. The Weberian mechanism is designed to conduct vibrations and not to register variations of pressure. The nerve-ganglion regulates tension of anterior sac and thus allows it to receive vibrations: it controls the sphincters and prevents undue lowering of tension when the pneumatic duct is open, and excess of tension due to pressure of gas in the posterior sac.—J. S **Huxley** Studies on amphibian metamorphosis II. It is not always possible to induce metamorphosis of the axolotl by enforced air-breathing in a considerable number of specimens This may be due to genetic differences between strains When axolotls are so treated the dorsal fin falls over and fuses completely with the skin of the back By using urethane it was found possible to keep frog tadpoles in narcosis for 8-12 days If previously treated with thyroid, they metamorphosed as rapidly as controls An atmosphere of oxygen is deleterious to tadpoles, and retards metamorphosis A mixture of air and oxygen containing 40 per cent. oxygen allows metamorphosis to proceed at the same rate as in air The dorsal fin of male newts which is developed in the breeding season is not caused to regress by administration of thyroid, unlike the larval fin-crest occupying the same position.—A. S **Parkes** and J. C **Drummond** Effects of vitamin-B deficiency on reproduction In a buck rat on a diet totally deficient in vitamin-B degeneration of testes and sterility ensue The amount of degeneration can be generally correlated both with degree of deficiency and time on the diet The fecundating power of the buck can be definitely correlated with degree of deficiency Size of litter, however, shows little variation. The proportion of males among the young decreases.—A **Dendy** On an orthogenetic series of growth forms in certain tetraxonid sponge-spicules. The so-called streptasters or siliceous spicules of the Theneidæ and Pachastrellidæ are not asters, and the spirally twisted axis which they exhibit is not an elongated centrum They are really derivatives of the primitive triact, which have arisen in accordance with a remarkable law of growth. These spicules, for which the name "dichotriacts" is proposed, appear to form an orthogenetic series of growth-forms, probably representing both a phylogenetic and an ontogenetic series. As in true asters, the increase in the number of rays is accompanied by diminution in size.—C. E. **Walker** The meiotic phase in Triton (*Molge vulgaris*). As is the case in the ordinary somatic mitoses, the univalent filament splits in the telophase of the somatic division immediately preceding the 1st meiotic (heterotype) division. These semivalent threads rejoin in the early prophase; the univalent filaments thus formed join longitudinally, and at the anaphase whole somatic chromosomes are distributed to the daughter cells. The splitting of the univalent filament in the telophase of the last somatic division is not consummated until the 2nd meiotic division, when the chromosomes split into longitudinal halves. The 1st meiotic division is a unique phenomenon interpolated between two mitoses providing for the equal distribution of whole chromosomes.—W. E. **Alkins**: *Clausilia bidentata* (Ström) and *Cl. cravenensis* (Taylor): a statistical inquiry into the relationship of two similar species. *Clausilia bidentata* is widely spread in Britain and elsewhere; *Cl. cravenensis*

occurs only in a restricted area in the north of England, and its specific status has generally been questioned. The altitude, diameter, and diameter/altitude ratio in series of each species collected from limited loci in which both species live together in the same habitat, have been studied While both species, and especially *bidentata*, are highly variable, and though local races may be distinguished within *cravenensis*, the two forms are clearly separated by biometric criteria, and there is no evidence of intermediate forms.

Royal Microscopical Society, December 17.—F. W Rogers **Brambell**: The part played by the Golgi apparatus in secretion and its subsequent reformation in the cells of the oviducal glands of the fowl The Golgi apparatus in the *cells of the alveolar glands* undergoes hypertrophy during periods of activity and reduction during periods of rest. It is not extruded with the secretion The *ciliated epithelium* lining the entire oviduct is also secretory During secretion the nucleus moves down the cell towards the lumen and the Golgi apparatus fragments, and is extruded from the cell The nucleus then moves to the back of the cell and the Golgi apparatus reforms *de novo*. The albumen of the egg of the bird is homologous with the envelope of mucus formed around the egg of the mammal in the Fallopian tube. In this respect the egg of Ornithorhynchus and the marsupials is intermediate The changes in the oviduct of the fowl between the laying of two successive eggs are comparable to the changes in the non-pregnant uterus of the mammal during the œstrous cycle.—R J **Ludford**: Some modifications of the osmic acid methods in cytological technique By treating suitably fixed tissues, after osmication, for 14-21 days with water at 35°-40° C., a good general impregnation of the Golgi apparatus can be obtained Sections can then be stained to demonstrate the mitochondria and nuclear structures Before staining it is desirable to treat sections with 0·1 per cent potassium permanganate, followed by sulphurous acid, in order to bleach the cytoplasm

Geological Society, January 7.—A. K. **Wells**: The geology of the Rhobell Fawr district (Merionethshire) The area described covers some 30 square miles centred about the mountain-mass of Rhobell Fawr The succession ranges from low down in the Lingula flags to the Bala mudstones. A feature of special interest is the development of an igneous cycle at a lower level than anywhere else in North Wales. The centre of eruption of which Rhobell is the denuded basal wreck, was a subaërial volcano which became active during the pre-Arenig interval Basic intrusions are common at several horizons between the Dolgelly beds and the Upper Acid group, and are without exception sills The area provides good illustrations of the action of an intrusive magma in persistently flooding certain horizons and invading selected rocks while leaving others unaffected. As a consequence of its position at the south-eastern "corner" of the Harlech dome, the strike changes almost through a right-angle in passing from south to north. Folding along north-and-south axes is dominant, but the folds have been buckled against the Rhobell mass, which acted as a resistant knot lying in advance of the hard core of the dome. The area is much faulted, the most important dislocations being parallel to those recently described from the Bala district

PARIS

Academy of Sciences, January 12.—A **Lacroix**: The meteorite of Roda. A detailed mineralogical and chemical analysis of this meteorite is given, which only differs from the terrestrial harzburgites by containing a higher proportion of iron.—Charles **Richet**, Eudoxie **Bachrach**, and Henry **Cardot**: The heredity of acquired characters proved by the displacement of the thermal optimum A normal strain of lactic bacillus has a maximum development at a temperature of 36° C. A strain of this bacillus, grown for three years in the presence of potassium chloride, has the optimum temperature raised by 6° C. to 42° C.; and this change persists and is characteristic of this strain of bacillus.—C. **Camichel**, L. **Escande**, and M. **Ricaud**: Overflow weirs.—Paul **Vuillemin**: A normal classification, auxiliary classification, and practical grouping of the fungi.—Bertrand **Gambier**: The invariants of Gauss, Beltrami, and Minding.—A **Kolmogoroff**. The axiomatic definition of the integral.—M. **Lavrentieff**. The sub-classes of the classification of M. Baire.—V **Weniaminoff**: The limit-derivative of an analytical function.—Maurice **Roy**: The adherence of a perfect liquid to a solid which it wets and Lagrange's theorem.—Georges **Patart** The influence of the cooling of a gaseous fluid previous to its compression A demonstration of the advantages of a preliminary cooling of gases before compression.—Emile **Belot**. The movement of a vortex in a resisting medium: application to planetary vortices.—Rafael de **Buen** The influence of the surface temperature on deep thermal changes in the western Mediterranean A discussion of the experimental data given by Richard, Oxner, and Sirvent.—H. **Eyraud** The projective Riemann character of the electromagnetic gravific field.—A. **Perot**. A photographic recorder and oscillograph.—Léon and Eugene **Bloch**: The spark spectrum of tungsten in the Schumann region A catalogue of wave-lengths and intensities of tungsten lines between $\lambda = 1826$ and $\lambda = 1453$.—Charles **Chéneveau**: The formation of optically disturbed media by the penetration of a transparent liquid into a transparent resin.—Jean **Thibaud**. Research on characteristic gamma spectra by crystalline diffraction. The method employed was that of the rotating crystal (velocity less than 1° in 24 hours) and Broglie photographic recorder. The γ spectra were obtained as fine lines without signs of any continuous bands. The crystal diffraction method furnishes a good confirmation of the values attributed to the γ frequencies by the method of excited β spectra.—Fred **Vlès** and Mlle. Madeleine **Gex**: The ultra-violet absorption of petrols. A study of the changes produced in the absorption bands by fractional distillation.—H. **Pélabon**: The direct formation of the mercury oxychlorides. The three oxychlorides, $HgO \cdot 2HgCl_2$, $2HgO \cdot HgCl_2$, $4HgO \cdot HgCl_2$, can be formed directly from HgO and $HgCl_2$ in the presence of water and of alcohol if the temperature is low. The first of these is white and is not formed if the temperature rises above 30° C., but once formed, can be heated to 100° C. without decomposition.—Emile **Luce**: Researches on the migratory aptitudes of the α-naphthyl radicle.— — **Royer**: The rotatory power of cholesterol bodies.—E. **Fournier**: A mode of capture by subterranean erosion, special to certain closed basins of the chain of the Jura.—Ch. **Gorceix**: The metric proof of the ovoid form of the earth. The ovoid proposed as the best representation of all the available geodesic measurements is intermediate between the ellipsoids of Clarke (1880) and **Bessel** (1841).—Jean **Piveteau**: The existence of a reptile with lacertilian affinities in the permian formations of Madagascar. The name *Broomia Madagascariensis* is given to this reptile, which is represented by a large number of well-preserved examples, only the head presenting difficulties.—G. **Mangenot**: The

mode of formation of starch grains in the latex of the Euphorbiaceæ.—Maurice **Lenoir**: The telophase of the first division in the embryonic sac of *Fritillaria imperialis*.—Vittorio **Pettinori**. The toxic action of *Amanita phalloides*. This poison acts not only on vertebrates, but also on infusoria, small crustaceans, the larvæ of insects and fishes. It has no action on the isolated heart of the frog, and probably is without action on lizards and frogs.—Gilbert **Ranson**: The cause of the green coloration appearing on oysters. The pigment of *Navicula ostrearia*, which is unaffected by the digestive juices of the oyster, is shown to be the cause of the green coloration.—Harry **Plotz**: Some observations on the mechanism of serum anaphylaxy. In anaphylaxy produced by serum injection two factors intervene: the physico-chemical state of the serum used for the sensitising injection, and the physico-chemical state of the second injection.—Georges **Bourguignon** and Mlle. Renée **Déjean**: Double chronaxy of the optical system in man.—Jean **Camus** and J. J. **Gournay**: Researches on diabetes and diuresis.

MELBOURNE.

Royal Society of Victoria, November 20.—J. **Ewart**. Stock poisoning in the Northern Territory. Along the main stock route in the Northern Territory very heavy losses of stock have been experienced in recent years and their cause has been in doubt. The cause was determined, by actual experiments carried out in Central Australia on a herd of cattle, to be poisoning due to *Indigofera boviperda*, the indigo cattle bane, and to *Isotropis atropurpurea*, the poison sage. The former is well known as a cattle-killer in Western Australia, but was not previously recorded as killing stock in the Northern Territory. It loses its poisonous properties when dried in a hot sun, owing to the ready decomposition of its alkaloid "cygnin". The Isotropis was not previously recorded as a poisonous plant. It is less poisonous than *Indigofera boviperda*, but the poison is more stable. An extract obtained by Dr. Young is poisonous to guinea-pigs, but the nature of the poison is as yet unknown.—C. **Fenner**: The Bacchus Marsh basin, Victoria. At a period somewhat earlier than middle Tertiary, the whole of Eastern Australia, including Victoria, consisted of low undulating highlands and vast level plains, well wooded and well watered. Under these conditions great brown coal deposits of Victoria, etc., were built up. Later there came some differential uplift of the land, and associated with this there was an outpouring of basaltic lava (the "older basalts"), and about this time the subsidence of Bass Strait possibly commenced. Later, there was another volcanic period (the "newer basalts"); these flows dammed up many of the streams, and filled up some of the old valleys, forming lakes and twin streams and causing a complete change in the drainage system. The faulting which followed or accompanied this volcanic period gave rise to the great mountain system of Eastern Australia. Locally it caused additional alteration in the stream activities. Thenceforward the natural downward cutting, side-swinging, and headward erosion of the Bacchus Marsh streams brought about the formation of the basin as it exists to-day.—A. H. **Coulson**: Geology of the Coimadai area, Victoria, with special reference to the Limestone series. Lower Ordovician and Permo-Carboniferous glacial rocks form the basement of the area, but the paper is concerned with the Kainozoic rocks. These comprise gravels, sands, etc., monchiquite dykes and basalt. The limestone, or more properly dolomite, contains fossils and a very finely laminated mudstone with small grains which bear a strong resemblance to the pollen grains of Pinus. The grains sometimes have a quadrate centre and at others there is a suggestion of spines and wings. The fossils are all referable to the Pleistocene. The extreme uniform fineness of grain and the absence, with one or two possible exceptions, of calcareous organisms, suggest that the dolomitic limestone is the result of deposition of a chemical precipitate of magnesian limestone and differential leaching, in places, giving a more magnesian limestone. Basaltic lava flows followed the sedimentation in the lake, but were preceded by the outburst of a fine ash which has only been found in the limestone lake. The outpouring of basalt completely altered the drainage system of the area. Pyrete and Goodman's Creeks came into existence and deposited, in their initial stages, high level gravels as a capping over the older rocks. In deepening their channels they carried away much of the softer gravels of the old "Bullengarook River," destroyed the limestone lake, and removed most of the limestone, the remnant of which is now covered by the higher gravels of these streams.

Official Publications Received.

Carnegie Institution of Washington. Year Book No. 23, November 1, 1923, to June 30, 1924. With Administrative Reports through December 12, 1924. Pp. xx+433+325. (Washington, D.C.)

Diary of Societies.

SATURDAY, FEBRUARY 21.

BRITISH PSYCHOLOGICAL SOCIETY (at University College), at 3.—Miss Isabel Burnett: Motives in the Acquisition of Skill.—Prof. T. H. Pear: On Forgetting the Unpleasant; An Examination into Recent Criticisms of Psycho-analysis.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—W. Rothenstein: The Artist's Relation to Social and Religious Life (II.).

PHYSIOLOGICAL SOCIETY (at London School of Medicine for Women), at 4.—G. Briscoe: Pressure of Phrenic Effects on Conduction of Respiratory Impulses.—E. E. Hewer and M. F. Lucas-Keene: Histological Preparations of certain Fœtal Tissues (Human).—J. W. Pickering: The Supposed Deficiency of Pro-Thrombin in Hæmophilic Blood.—W. Cramer: The Process of Secretion in the Thyroid Gland.—J. F. Fulton: Plurisegmental Innervation of Single Muscle Fibres (Frog).—A. St. G. Huggett and Prof. J. Mellanby: Preparation and Properties of Secretin.—R. E. Havard and G. A. Ray: The Effect of Exercise on Blood Phosphate.—J. B. S. Haldane: Some Effects of Ingesting $MgCl_2$ and $SrCl_2$.—A. D. Ritchie: Chloroform Rigor in Frog's Muscle.—J. H. Burn and H. Marke: The Relation of the Thyroid Gland to the Action of Insulin.—F. C. Kelly: The Effect of Iodine on the Metabolism

of Nitrogen and Phosphorus in the Growing Pig.—A. D. Kay and W. Smith: The Effect of Insulin on Blood Volume.—H. Florey: Microscopical Observations on the Cerebral Circulation.—D. Woodman: Effects of Parathyroid Feeding.—E. C. Pillman-Williams: Blood Nitrogen Values during Labour.

INSTITUTION OF MUNICIPAL AND COUNTY ENGINEERS (North-Eastern District) (at Municipal Buildings, Blyth), at 5.—L. Leeper: Five Years' Progress at Blyth.—J. L. Turner. The Law relating to the Collection of House Refuse and Trade Refuse.

MONDAY, FEBRUARY 23.

ROYAL IRISH ACADEMY, at 4.15.

ROYAL SOCIETY OF EDINBURGH, at 4.30.—Dr. B. N. Peach and Dr. J. Horne: The Scientific Career of Sir Archibald Geikie.

VICTORIA INSTITUTE (at Central Buildings, S.W.), at 4.30.—Prof. A. T. Clay: The Amaru.

INSTITUTE OF ACTUARIES, at 5.—F. L. Collins: Winding up a Life Assurance Company under the Provisions of Section 17 of the Assurance Companies Act, 1909.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Dr. G. W. De P. Nicholson: The Nature of Tumour Formation (I.).

INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting), at 7.—W. E. Warrilow and others: Discussion on the Electrical Journals, Past, Present, and Future.

INSTITUTION OF ELECTRICAL ENGINEERS (North-Eastern Centre) (at Armstrong College, Newcastle-on-Tyne), at 7.15.—H. W. Clothier: The Design of Electrical Plant, Control Gear, and Connexions for Protection against Shock, Fire, and Faults.

ROYAL SOCIETY OF ARTS, at 8.—Dr. W. Rosenhain: The Inner Structure of Alloys (II.) (Cantor Lectures).

ROYAL SOCIETY OF MEDICINE (Odontology Section), at 8.—F. N. Doubleday: Report upon Some Drugs and Solutions used in Local Anæsthesia.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—Sir Gerald Lenox-Conyngham: The Great Barrier Reef.

MEDICAL SOCIETY OF LONDON, at 8.30.—Sir G. Lenthal Cheatle: The Early Stages of Pathological Hyperplasia in the Breast, with special reference to Cysts and their Danger.

TUESDAY, FEBRUARY 24.

ROYAL DUBLIN SOCIETY (at Royal College of Surgeons, Dublin), at 4.15.—Prof. F. E. Hackett and others: Discussion on Modern Theories of Atomic Structure.

ROYAL SOCIETY OF ARTS (Dominions and Colonies Section), at 4.30.—R. H. Brackenbury: Transport in Tropical Africa.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.15.—Prof. J. Barcroft: The Colour of the Animal Creation (III.): The Colour of the Chameleon.

ROYAL SOCIETY OF MEDICINE, at 5.30.—General Meeting.

INSTITUTION OF CIVIL ENGINEERS, at 6.—L. H. Savile: The Demolition of the Harbour and Defence Works of Heligoland.

INSTITUTION OF AUTOMOBILE ENGINEERS (Informal Meeting) (at 83 Pall Mall), at 7.—Discussion on Curious Breakdowns.

INSTITUTION OF ELECTRICAL ENGINEERS (North Midland Centre) (at Hotel Metropole, Leeds), at 7.—T. D. Trees: Selection of Ball and Roller Bearings for Electrical Machines.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—E. C. D. Hickman: Colour and the Psychology of the Kinema.—O. Bloch: A Daylight Viewing and Projecting Filter for Autochrome Plates.—Miss Catharine O. Stevens: A Plea for the Kinematography of Wind Waves.

INSTITUTION OF AUTOMOBILE ENGINEERS (Coventry Graduates' Meeting) (at Broadgate Café, Coventry), at 7.15.—R. N. Aveline: The Testing of the Automobile.

INSTITUTION OF ENGINEERS AND SHIPBUILDERS IN SCOTLAND (at 39 Elmbank Crescent, Glasgow), at 7.30.—H. H. Blache: The Latest Type of the Burmeister and Wain Diesel Engine.

ROYAL ANTHROPOLOGICAL INSTITUTE (at London School of Economics), at 8.15.—L. H. Dudley Buxton: The Stoney Indians of the Bow River, Alberta.

WEDNESDAY, FEBRUARY 25.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Dr. G. W. De P. Nicholson: The Nature of Tumour Formation (II.).

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Prof. A. H. Cox: (*a*) The Geology of Cader Idris (Merionethshire), (*b*) The Dissection of Pitching Folds.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Graduate Section) (at *Mining Institute, Newcastle-on-Tyne*), at 7.15.—Prof. T. H. Havelock: The Principle of Interference in Ship-waves and Ship Resistance.

INSTITUTION OF ENGINEERS-IN-CHARGE (at St. Bride Institute, Bride Lane, E.C.), at 7.30.—Discussion on Responsibilities and Difficulties of the Engineer-in-Charge.

ROYAL MICROSCOPICAL SOCIETY (Industrial Applications Section), at 7.30.—Dr. J. A. Murray: The Making of Microscopical Preparations (I.): Wet Preparations.—F. Summers: Applications of the Microscope in Textile Research.—T. B. Bright. Methods of Examination of Mildewed Cotton Material.

ROYAL SOCIETY OF ARTS, at 8.—Sir Dugald Clerk. The Power of Internal Combustion Engines for Motor Cars.

BRITISH PSYCHOLOGICAL SOCIETY (Medical Section) (at Royal Society of Medicine), at 8.30.—Dr. N. H. M. Burke: Some Aspects of the Interrelation between Bodily and Mental Disease.

INSTITUTION OF AUTOMOBILE ENGINEERS (North of England Centre) (at Liverpool).

THURSDAY, FEBRUARY 26.

ROYAL SOCIETY, at 4.30.—Prof. E. H. Starling and Dr. E. B. Verney: The Secretion of Urine, as studied on the Isolated Kidney.—F. Bickhoist and Prof. E. H. Starling: The Action of Inorganic Salts on the Secretion of the Isolated Kidney.—Dr. G. V. Anrep: A New Method of Crossed Circulation.—Dr. G. V. Anrep and I. de B. Daly: The Output of Adrenaline in Cerebral Anæmia, as studied by means of Crossed Circulation.—Dr. G. V. Anrep and Prof. E. H. Starling: Central and Reflex Regulation of the Circulation.—K. Furusawa: Muscular Exercise, Lactic Acid and the Supply and Utilisation of Oxygen. Part IX. Muscular Activity and Carbohydrate Metabolism in the Normal Individual.—*To be read in title only*:—A. Hunter and J. A. Dauphinee: (*a*) Quantitative Studies concerning the Distribution of Arginase in Fishes and other Animals; (*b*) An Approximative Colorimetric Method for the Determination of Urea with an Application to the Detection and Quantitative Estimation of Arginase.—Dr. J. J. R. Macleod and N. A. McCormick: The Effect on the Blood Sugar of Fish of various Conditions, including Removal of the Principal Islets (Isletectomy).

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.15.—Sir Arthur Smith Woodward. Dinosaurs (I.).

INSTITUTION OF AUTOMOBILE ENGINEERS (Luton Graduates' Meeting) (at Luton), at 7.30.—W. B. Draper: The Balancing of Automobile Engine Crank Shafts.

CHEMICAL SOCIETY (at Institution of Mechanical Engineers), at 8.—Sir William B. Hardy. Problems presented by Films on Solid Surfaces.

INSTITUTION OF STRUCTURAL ENGINEERS (at 296 Vauxhall Bridge Road), at 8.—E. Godfrey: Reinforced Concrete Columns.

INSTITUTION OF MECHANICAL ENGINEERS (Birmingham Section).

FRIDAY, FEBRUARY 27.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 5.—J. J. Manley: Notes concerning the Sprengel Pump.—J. Young. The Thomson Effect in Copper, Iron, and Carbon Steels.—D. W. Dye: Improved Cathode Ray Tube Method for the Harmonic Comparison of Frequencies and for the Delineation of their Wave Form.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Dr. G. W. De P. Nicholson. The Nature of Tumour Formation (III.).

SOCIETY OF CHEMICAL INDUSTRY (Glasgow Section) (at 39 Elmbank Crescent, Glasgow), at 7.—J. Mitchell: Research in Industry.

INSTITUTION OF MECHANICAL ENGINEERS (Informal Meeting), at 7.—Discussion on Practical Problems of Lubrication.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—H. Pickwell: The Monuments and Fountains of London.

INSTITUTION OF AUTOMOBILE ENGINEERS (Graduates' Meeting) (at Watergate House, Adelphi), at 7.30.—R. Marks: Why Pneumatic Tires?

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—E. Stroud: A Treatise on Modern Lighting Practice.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (at Literary and Philosophical Society, Newcastle-on-Tyne), at 7.30.—Prof. A. L. Mellanby and Dr. W. Kerr: Limiting Possibilities of Steam Plant.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Middlesbrough Branch) (in Cleveland Scientific and Technical Institution), at 7.30.—G. M. Harroway: The Problem of the Workshop.

EUGENICS EDUCATION SOCIETY (at Royal Society), at 8.30.—Dr. B. Malinowski: Mate Selection in Primitive Society.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Sir James C. Irvine: Sugars from the Standpoint of the Organic Chemist.

SATURDAY, FEBRUARY 28.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: The Counting of the Atoms (I.).

PUBLIC LECTURES.

SATURDAY, FEBRUARY 21.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—F. Balfour Browne: My Journey to Brazil.

MONDAY, FEBRUARY 23.

LONDON SCHOOL OF ECONOMICS AND POLITICAL SCIENCE, at 5.—Dr. E. B. Behrens: International Problems of Industry: Problems of the Future.

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY (Royal School of Mines), at 5.15.—Prof. L. Denoël. Tubbing Deep Shafts and Subsidence. (Succeeding Lectures on February 24, 25, 26.)

BIRKBECK COLLEGE, at 5.30.—Dr. G. G. Coulton: Medieval Education (IV.): The Medieval University.

KING'S COLLEGE, at 5.30.—Prof. W. T. Gordon. The Geological History of Plants (Swiney Lectures). (Succeeding Lectures on February 25, March 2, 4, 9, 11, 16, 18, 23, 25, 30, April 1.)

TUESDAY, FEBRUARY 24.

KING'S COLLEGE, at 5.30.—Prof. W. J. De Burgh: Neo-Platonism and Christianity.

GRESHAM COLLEGE, at 6.—Prof. W. H. Wagstaff: Geometry (Gresham Lectures). (Succeeding Lectures on February 25, 26, 27.)

LEEDS UNIVERSITY, at 8.—Prof. W. Garstang. Animal Life on the Yorkshire Coast.

WEDNESDAY, FEBRUARY 25.

LONDON SCHOOL OF ECONOMICS AND POLITICAL SCIENCE, at 5.—C. H. C. Baker: The Principles of Design as applied to our Homes.

ROYAL SOCIETY OF MEDICINE, at 5.—Prof. R. Cruchet: The Relation of Paralysis Agitans to the Parkinsonian Syndrome of Epidemic Encephalitis.

KING'S COLLEGE, at 5.30.—Dr. Eileen E. Power: Travel and Travellers of the Middle Ages (VII.): The Opening of the Land Routes to Cathay, A.D. 1200–1350.

THURSDAY, FEBRUARY 26.

UNIVERSITY COLLEGE, at 5.—G. A. Sutherland: Auditorium Acoustics. (Succeeding Lectures on March 5, 12.)—At 5.15.—Sir Henry Hadow: The Place of Music in University Education.

KING'S COLLEGE, at 5.30.—Prof. E. W. Scripture: German Poets and their Verse.

SATURDAY, FEBRUARY 28.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—W. J. Perry: The Ancient Mariners of the Pacific.

SATURDAY, FEBRUARY 28, 1925.

Words, Meanings, and Styles.

II.

THE first element of good style is clearness, and this may or may not be combined with literary elegance. It is usual to regard a split infinitive as a sign of indifference to pure English, yet this misplacement will be found in the works of some of our leading writers. The practice is discussed in an open-minded manner in Tract No. XV. recently published by the Clarendon Press for the Society for Pure English; and though no precise conclusions are reached whether it is permissible or no, the general view taken is that when a split infinitive is the best form of avoiding ambiguity it can be justified It is admitted that the separation of *to* from its infinitive is not in itself desirable, but, on the other hand, obvious artificiality may be introduced when the practice is regarded as a fetish. "To see clearly" is certainly preferable to the split infinitive "To clearly see"; and "To be clearly seen" or "To be seen clearly" to the form "To clearly be seen," but it is difficult sometimes, without splitting the infinitive, to retain the meaning desired. Thus, the pamphlet referred to gives as an example the phrase "we must expect the Commission to at least neglect our interests." To place the words "at least" anywhere else in the sentence would not convey exactly the same idea, and instead of changing their position it would be better to recast the sentence. People who deliberately avoid split infinitives have often an objection to divide a compound verb by adverbs, so that they would write "earnestly may be hoped" instead of "may be earnestly hoped." There is, however, no grammatical reason against such splitting as there is in splitting an infinitive; indeed, the proper place for the adverb is between the auxiliary and the principal verb.

From the point of view of correct grammar, the conjunction "and" ought not to be used to begin a sentence, in spite of its common use in this place in the Authorised Version of the Bible. The function of the word is to add one word or clause to another in a sentence, and this rule is broken when the word opens a new sentence. The incorrect use of "and which" is very common. Generally, either the pronoun or the conjunction should be omitted, or the former is misplaced. When entirely different statements are expressed by two clauses of a sentence, or the cases are different, the relative may be repeated, but not otherwise. Thus it is correct to write, "The results, which support my earlier views, and which I will describe," or "His work on behalf of the scientific world, which he has served so well, and which esteems him so highly," but not "These phrases, which are irritating to read, and which are met every day," or "It is a principle

which is easily understood and which is also easily forgotten." The best way to avoid flagrant errors in regard to the use of "and which," "but which," "and who," and similar combinations, is to omit whatsoever word is intrusive or redundant That is, indeed, the touchstone by which most questions of literary style may be tested

As to particular words and phrases, some of these in common use are indefensible, while the use of others must be left to personal taste to decide It is fatuous to write "to the foot of the letter" instead of "literally," and clumsy to use "it goes without saying" for "it need scarcely be said" or "needless to say" "In the circumstances" is obviously a more correct phrase than "under the circumstances," and "to direct attention" is preferable to the usual form "to call (or draw) attention" "Last," which denotes position, should not be used in the sense of "latest," which signifies time To use the word "phenomenal" to describe remarkable things or events having nothing to do with phenomena is to adopt inept journalese of the same type as the use of the verb "to transpire" in the sense of "to happen" For the use of "over" in the sense of "more than" there is no justification; and "scarcely" is always the correct word to use instead of "hardly" in expressing quantity. "To try an experiment" for "to make an experiment" is, of course, wrong. "After" or "later" is usually preferable to "subsequently"; "total" or "whole" to "aggregate", "viewpoint" or "point of view" to "standpoint", "first" to "firstly"; "person" to "individual" except where a single or separate person is specified; "common" to "mutual", "largely" to "materially"; and there are many other preferences of a like kind.

Purists object strongly to the word "reliable" because of its irregular formation, though the same objection can be made to the words "laughable" and "indispensable." Some authors make the distinction of applying the word "reliable" to things or statements, and "trustworthy" to persons, and that is the general practice followed in these pages. It would be pure pedantry to refer to an engine as "trustworthy" instead of "reliable," and stupidity to describe "reliability tests" as "trustworthiness tests." Mr. B. J Hayes, writing from Burlington House, Cambridge, objects to the use of the word "humanoid" in NATURE of February 7 (p. 201, bottom of column 1), and suggests that "hyperanthropoid" would make the use of the hybrid word unnecessary. His word, however, though correctly formed, would signify that the type referred to as humanoid was in the same direct line of development as anthropoid, whereas it belongs to a separate line.

Most of these distinctions are, however, relatively minor matters from an editorial point of view compared with diversities of paragraphing, punctuation, use of capitals, inaccuracy of quotation, and incorrect references, which come under consideration every day. It is, of course, undesirable to insist upon a uniform style of paragraphing or punctuation; and all that we would urge is that long paragraphs and long periods put too much strain on the powers of attention of the reader. There is little possibility, in scientific articles, of offending in the other direction by over-shortening paragraphs and periods until they reach the staccato style of the sprightly part of the daily press

A quotation may be used as an apt illustration of a particular point, or as a statement of the nature of evidence on one side or the other bearing upon the case upon which judgment is being expressed Of the former class, the authors of "The King's English" describe as trite: balm in Gilead, *e pur si muove*, a consummation devoutly to be wished, the irony of fate, the psychological moment, the pity of it, and many others; and they give the following among common misquotations, the corrections being in brackets: A *poor* thing, but mine own (an ill-favoured), *small* by degrees and beautifully less (fine), *the* last infirmity of noble *minds* (that, mind); make assurance *doubly* sure (double); a goodly apple rotten at the *core* (heart).

We are, however, more concerned with material than with formal quotations, and our experience is that very many writers fail to realise the necessity of reproducing with literal accuracy the extracts they quote, whether for approval or criticism. The number of variations which writers make, deliberately or inadvertently, from the original text is really astonishing to any one who goes to the trouble of verifying what is quoted. It cannot be too strongly insisted upon in a scientific journal that not merely the sense but the actual words and form should be reproduced exactly in a quotation, and that punctilious care should be taken in this respect when the quotation is from a book under review, or from a contribution upon which comments are being made. No wiser advice could be given than that of "verify your references," whether these signify volumes, dates, and pages, or actual quotations.

While an editor can scarcely be held responsible for the accuracy of all the quotations made by his contributors, it is his duty to secure reasonable uniformity in various elements of grammatical and typographical style. For example, certain collective nouns, such as Ministry, Government, Council, Board, Commission, Committee, are used by some writers with a singular verb and by others with a plural. In official practice the plural is commonly used, as "The

Ministry have decided"; here the noun signifies the members of the Ministry and its sense is, therefore, plural. When, however, plurality is not intended, and reference is to a single body, it would seem to be equally correct to use a singular verb. We prefer the verb and the pronoun to be singular, as with a "nation" or "people," where they are always used rightly. On the other hand, nouns like the United States, Physics, and Mathematics, though plural in form are singular in meaning and a singular verb is, therefore, used with them. Here it is not a matter of preference or consistency but of accurate diction.

This brings us to the use of capitals, and there does not seem to be any general rule for capitalisation other than that of the initial letter of the word beginning a sentence Some authors tend towards the German style of writing every noun with an initial capital, but few follow a definite plan, and it is left to editors or printers to secure reasonable uniformity in this respect. Our custom is to use capitals in Latin scientific names of orders, genera, and so on, but not in corresponding English words Thus, we should print Coniferæ, but without the capital letter in conifers, and similarly, Amphibia or amphibians, Crinoidea or crinoids. Every week, however, brings difficulties in the application of any general rule to contributions of different authors, and we have to exercise the editorial prerogative in deciding whether initial capitals should be used or no in such words and terms as Radium-D, Department, Faculty, State, Parliament, Superintendent, Director, Report, Tertiary age and Stone Age, Neolithic Man, Miocene Period and Celtic period, London Clay (or clay), Ångstroms, Theory of Relativity, Quantum Theory, Correspondence Principle, names of elements and minerals, and a host of other examples of a similar kind.

In general, our rule is to use initial capitals only when specific institutions, bodies, divisions, and so on, are referred to, and not when these are described in a generic sense. Thus, we should print, the University of Cambridge, but British universities; the British Scientific Instrument Research Association, but industrial research associations; the House of Commons, but the state legislature; the Middlesex Education Committee, but local education authorities; the State of New York, but the northern states; the Galaxy, but the stellar universe. It may be said, therefore, that initial capitals are used only when they are positively necessary for precise description, and are avoided unless there is an essential reason for them. We realise that our decisions are sometimes purely arbitrary, but in the absence of established principles they cannot be otherwise.

There is only one other matter to which we wish to refer in concluding this discursive article: it is that of the common belief that writers on scientific subjects compare unfavourably with workers in other intellectual fields in the capacity to express themselves in suitable words, or in their appreciation of good English. We cannot accept this view for a moment, and we resent strongly the supercilious attitude which literary people often present towards scientific works. It seems to be taken for granted by some writers who survey published literature from week to week, that no work of science can possibly be classed as literature. We do not hesitate to say, however, that, judged by literary standards alone, scientific books are published every week more worthy of comment than many of those selected to represent the week's literature Though classical scholars and men of letters may not think it derogatory to be without a knowledge of science, most men of science are familiar with one or two languages in addition to their own, and they have, at any rate, a certain acquaintance with the art of literary expression and often the desire to perfect themselves in it The vocabulary of a man of science is probably more extensive than that of a man of letters of equal authority, but it includes many technical words which are understood only by workers in particular fields and cannot be used effectively, therefore, when addressing a wider circle.

That is the chief distinction which need be made between scientific articles and books and those of a purely literary kind It is not necessary for a chemist who is writing for chemists to describe the scientific words and phrases he uses any more than it is for the literary man to explain his allusions, or the historian the significance of his periods and characters. When, however, a chemist is addressing the world of science as a whole, he must avoid the special language of his branch of science if he is to be intelligible, and if he is writing for the general public he has to do so in everyday words and phrases. The standard of suitability of contributions to *Chemistry and Industry* differs, therefore, from that of a general scientific periodical such as NATURE, and this differs again from that of a daily newspaper or of a parish magazine. It ought not, however, to be too much to expect in these days that educated men and women should be acquainted with words and phrases which are part of the common vocabulary of science; and if that desideratum be granted, we may safely claim that the writings of many men of science are truly literary in style as well as scientific in substance, while as regards originality of fact and idea, they are far in advance of all other published works

The Australian Opal.

Opal: the Gem of the Never Never By T. C. Wollaston. Pp. xi+164+15 plates. (London: T. Murby and Co., 1924.) 10*s.* 6*d.* net.

OF precious gems the opal and the pearl take pride of place, for they seem to become part of their wearers, throwing up their beauty and receiving from them additional lustre. Our author has tried both, for he once ran a pearling fleet from Torres Straits to Timor-Laut, but sold out in favour of developing the opal, which seems to him "to be alive and almost as precious as a rose or daffodil." This expresses the motive of the book, the author a naturalist first—a true Wollaston—secondarily, the exploiter of the Australian gem, which he clearly regards as primarily connected with living organisms.

The opal is usually described as an hydrated silica which has consolidated unequally, contracting in different directions. It shows iridescent reflections from surfaces, irregular both in dimensions and arrangement, which by some authorities have been regarded as microscopic pores, arranged parallel (Crookes), while others suppose the inclusion of thin laminæ of foreign substances of different indices of refraction (Behrens), this meaning rich interference phenomena. The amount of water varies up to 13 per cent., and the product fluctuates from a colourless or black glassy substance to the most wonderful play of colours. There has, however, been little recent research on the opal, and these statements as to its structure are based on Hungarian, Mexican, and Honduras stones, which are not necessarily the same in structure as the Australian.

The position would seem to be that there was a sea which in Cretaceous times connected the Gulf of Carpentaria and the Great Australian Bight. It extended over the western halves of Queensland and New South Wales and covered most parts of the Northern Territory and South Australia, ending to the west at an undefined line in Western Australia. Then came the upheaval and the whole was covered with a desert sandstone. This has mostly disappeared by denudation, but its remains are found in a line of low ranges and tablelands down the middle of Queensland and New South Wales, close to the eastern edge of the desert; there is also a big patch, Coberpedy, in the centre of South Australia. These are the bare bones of facts, which the author amusingly clothes throughout his book with an unblushing and charming fantasy.

Everywhere in this desert, sandstone is found showing a tendency to opalisation, but the precious opal occurs principally in its basal part in a thin band or "casing" over underlying clay. Concretionary boulders or nodules of siliceous ironstone are also found containing precious opal, but a usual occurrence in the sandstone is in pipes of about the length and thickness of a pencil; these frequently show colour repetitions along their lengths, more likely, we think, to be metameric repetitions in deposition than due to "unequal pressure." All sorts of cracks and crevices in the sandstone are filled up, and the best colours are frequently shown in small sheets, only 1 to 2 mm. thick.

At the British Empire Exhibition at Wembley the author and others showed an immense variety of specimens. Some were opalised wood, while opals in spaces naturally formed in the decay of wood were also shown. Then there was a great variety of bivalve and coiled shells, some of which appeared to have the shell replaced by opal, but most, perhaps, were rather of the nature of casts. Some specimens, particularly of the blackest opal, on superficial inspection irresistibly suggested sponges and corals. Yet in others, more transparent, transmitted light revealed dark mossy growths, bearing a peculiar resemblance to the boring growths of algæ and sponges in coral, as seen after decalcification. Then there were numerous casts of the small bones and vertebræ of reptiles and of fish, in some cases surrounded by actual bone. Most of the opal had no visible connexion with organic remains, but yet, as our author points out, nearly all Australian opal has a pattern of some sort in it, often in squares or parallel lines; the colour boundaries, too, are generally determinate. Metameric repetition is very usual in the structure of animals, and we saw much in these opals that suggested such structure, but it is hard to suppose that the basal opalised band is directly connected with former organic life. In any case, Mr. Wollaston's account and specimens leave one with the impression that the combined effects of light and structure, from which the opal derives its beauty, are quite probably not the same in the Australian as in the older known opals and demand further investigation, for which the author offers to put material at the disposal of competent researchers.

For the rest, the book contains no systematic and dry-as-dust account of the opal country; there are an extraordinarily interesting series of word pictures, painted with great freshness and vigour. We have rarely read a more vivid diary than that of a visit paid to the opal country in 1888, roughly 1000 miles from Adelaide along the eastern edge of the Great Desert, mostly camel-riding. The journey had all the elements of adventure about it, dangers of direction and of drought, but above all it is a picture of the

"Never-never" land as seen by a real man. Nature is sketched in with a full brush, and the result on the reader's mind is a vivid picture of one of the least known parts of the world, made interesting by a wealth of scientific problems, physical, geological, and biological, crying out for investigation. The many touches of fancy and personality, which make this book so suitable for popular reading, must not be allowed to obscure its value as a distinct contribution to knowledge. J. STANLEY GARDINER.

Endocrine Organs and Secretion.

(1) *The Endocrine Organs: an Introduction to the Study of Internal Secretion.* By Sir E. Sharpey-Schafer. Second edition. Part 1: The Thyroid, the Parathyroids, and the Suprarenal Capsules. Pp. ix + 175. (London: Longmans, Green and Co., 1924.) 15*s.* net.

(2) *An Introduction to the Study of Secretion.* By Prof. Swale Vincent Pp. 168. (London: E. Arnold and Co, 1924) 10*s.* 6*d.* net.

(3) *The Parathyroid Glands in Relation to Disease* By Dr. H. W. C. Vines. Pp. viii + 128. (London. E. Arnold and Co., 1924.) 10*s.* 6*d.* net.

SIR EDWARD SHARPEY-SCHAFER'S well-known book on the endocrine organs, which was founded on a course of lectures (Lane Medical Lectures) delivered at Stanford University in California in 1913, is being rewritten in two volumes, of which the first only (1) has so far been published. This volume deals with the general considerations of internal secretions and the organs which furnish them, and then proceeds to a detailed treatment of the thyroids, parathyroids, and suprarenal capsules. Part 2, which deals with the remaining endocrine organs, will appear later.

Part 1 of the new edition is rather larger than the whole of the first edition, and its greater bulk has been necessitated by a more complete description of the organs and their secretions, and by the addition of many excellent illustrations. The more important literature, and particularly recent literature, is given in footnotes on the pages on which it is referred to in the text. The references are numerous, and while they do not obtrude in any way upon the text, will be found very convenient to any one who wishes to consult the original papers. The literature on endocrinology is enormous, and wide knowledge, personal experience, and a critical judgment are required of any one who attempts to disentangle salient facts from hypothesis. No one is better qualified than the author to undertake such an analysis, for there are few problems in endocrinology of which he has not a first-hand knowledge. The result is a full, authoritative, yet not dogmatic presentation of the subject, which, when completed by the issue of Part 2, will make these volumes the standard work on the endocrine organs.

(2) Prof. Swale Vincent's book is an account of the process of secretion based upon a series of lectures given to medical students at the Middlesex Hospital during 1922–23. Much of it is of necessity elementary, but certain forms of secretion which do not appear in ordinary physiological literature are included, *e.g.* the secretion of gases by the gas bladders of teleostean fishes, hirudin by the leech, silk, the webs of spiders, poisons, the inky secretions of cephalopods, and the luminous substances of light-producing organisms. The anatomical and histological characteristics of the glands are fully described, and most of the illustrations in the book are of histological appearances

Much interesting matter has been collected by the author which has never been brought together before, but is of importance in a general consideration of the subject of secretion. Rather more than half the book deals with external secretion; the remainder is a short summary of the histology and processes of internal secretion.

The author reviews the methods which have been adopted for the investigation of the problems of internal secretion, and has some wholesome criticism to make of modern "organotherapy," a practice which is based upon the assumption that the active substance of the gland is absorbed unaltered into the circulation when administered by mouth. It may be objected that Prof. Swale Vincent is too critical, but in the absence of experimental proof that preparations of the ductless glands, other than thyroid, and, to a much less extent, the active substance of the Islets of Langerhans of the pancreas, have any action when administered orally, his is the only scientific attitude.

In regard to internal secretion generally, Prof. Swale Vincent also sounds a note of caution. It is by no means proved that all the organs classified as endocrine really exert their influence by secreting active substances into the blood, and because this is found to be true of one gland it does not follow that all act in a like manner. The parathyroids are specially mentioned as furnishing an example of a gland which, while it influences metabolism in certain directions, may do so, not by an internal secretion, but by an action comparable to that of the liver cells in their influence upon protein metabolism. One feels that the probability of action by an internal secretion is greater in the case of small glands like the parathyroids, but no harm is done in stressing the fact that much is assumed without proof in regard to the supposed functions of some of the ductless glands.

(3) Dr. Vines has undertaken a difficult task in compiling a monograph upon the parathyroid glands. The difficulty lies in the conflicting views which are held as to their functions At one time the parathyroids were confused with the thyroids, and most of the older literature is permeated with this error More recent views regard the glands as playing some ill-defined rôle in the metabolism of calcium salts, or as concerned with the detoxication of certain nitrogenous bodies, such as guanidine, normally formed in metabolism. Dr. Vines assigns both functions to the parathyroids, and considers they are carried out by different means. He gives an excellent summary of the different views put forward, and references to the more important original papers on the subject His conclusions, however, do not always carry conviction upon the evidence produced

Dr. Vines recognises that the means whereby calcium metabolism is controlled are very obscure and that other ductless glands may be involved. The evidence that the parathyroids are specially involved in calcium metabolism is far from satisfactory. The proofs of their having a detoxicating influence upon guanidine are more certain, and Dr. Vines has elaborated a method of testing this action *in vitro* A table is given showing the considerable variations which he found by this means in the activity of commercial preparations of parathyroid. The possible inactivity of parathyroid preparations is freely discussed, as also is the fact that parathyroid feeding in normal animals has no definite physiological effect. Dr. Vines does not agree with Prof. Swale Vincent that parathyroid therapy is therefore worthless, and gives experimental evidence that parathyroid feeding, even in small doses, has a distinct effect both in diminishing an excess of guanidine in the blood and in promoting an increase of calcium salts in the plasma of the human subject in certain pathological conditions

The difference of opinion is a fundamental one. Dr. Vines claims that a negative effect of parathyroid is to be expected in the normal animal, for in such case guanidine is not present in excess in the blood. Insulin, the active principle of the Islets of Langerhans of the pancreas, has a very potent effect upon the normal animal where there is no excess of glucose in the blood, but the analogy may not be a fair one. Until much more is known about the mode of action of the parathyroid and the nature of its active principle or principles, it is unsafe to express definite opinions. Such criticism is inevitable in the present lack of knowledge about the parathyroids, but is not intended to detract from the value of the work of Dr. Vines, who has rendered a distinct service to medicine in issuing this volume. P. T. H.

A Composite Work on Physical Chemistry.

A Treatise on Physical Chemistry. A Co-operative Effect by a Group of Physical Chemists. Edited by Prof. Hugh S. Taylor. In 2 vols. Vol. 1. Pp. xi+603+41. Vol. 2. Pp. ix+701-1359+41. (London: Macmillan and Co., Ltd., 1924.) 50s. net.

WHILST the group method of writing has in the past been confined almost exclusively to treatises in various branches of medicine and surgery, Prof. Taylor is to be congratulated on a most successful application of the method to physical chemistry. This subject, which unfortunately for Great Britain did not develop with such rapidity as its sister subjects pure chemistry and physics, is now entering a period of a new revival which renders the appearance of this work most opportune It is interesting to note not only a number of British nationality among the seventeen contributors to the various chapters, but also that uniform English spelling is adopted.

The volumes are conveniently so divided in subject matter that the first volume forms the basis for developing the more fundamental laws and properties of matter, whilst in the second a more advanced and in certain portions a somewhat speculative treatment of some of the newer aspects in the development of physical chemistry is presented.

Prof. Taylor has almost achieved the aim of the ideal editor in forming a composite text-book without serious change in either the standard or style of treatment from chapter to chapter The treatment of the gaseous and liquid states of aggregation in the first volume, and of colloid chemistry in the second, might possibly be singled out as somewhat inadequate; whilst the chapters on the solid state of aggregation and electrical conductance in the first volume, on the electro-chemistry of solutions, catalysis and the quantum theory in physical chemistry in the second volume, are really good both in clarity of expression and in the range of material covered.

The text is remarkably free from misprints, of which perhaps the most striking is Helmholz for Helmholtz, whilst Debrouste, p. 133, should surely read Labrouste.

In a book of this character a certain amount of repetition is unavoidable; one might suggest that perhaps a little too much space is given in the first volume to the discussion of Henry's law, which appears both on p. 238 and p. 344, and to the now exploded radiation theory of chemical change in the second.

In discussing dilute solutions in the first volume, the student is led on to the concept of activity and potential functions. If such a treatment were extended to the introduction of the phase rule, p. 367, the reading by

the student of books specially devoted to this subject would be greatly facilitated, whilst the plotting of the temperature as abscissa in the phase diagrams (Figs. 23 and 29) does not seem a very happy innovation.

It is a pity that the erroneous conceptions concerning the determination of the surface tension of solutions by the drop weight method are finding a place in standard text-books. Harkins' extension of Lohnstein's work on this subject might well be replaced by that of Iredale in a future edition.

The important paper of Debye and Hückel on the ionisation of strong electrolytes has been largely utilised in the second volume, and it would form a good substitute for the discussion of the erroneous hypothesis of Ghosh, to which three pages are devoted in Chapter xi. Also, in view of the ever-increasing importance of the amphoteric electrolytes, such as the proteins, a more detailed discussion of some of the electrical properties of such substances would not be out of place. In the chapter on colloid chemistry, Antonov's important rule and the alternative forms of the Gibbs' equation for non-ideal solutions might well have been included

One of the most valuable features of the book is the inclusion of a number of experimental methods, together with a discussion on the probable and possible errors in physical chemical measurements, which serves not only to emphasise the need for consideration of the accuracy of measurements obtained in the laboratory, but also assists the student in visualising the subject both in its theoretical and its practical aspects.

Prof. Taylor, his co-workers, and the publishers are to be heartily congratulated on the production of this text-book, which, at any rate on the desk of the reviewer, will replace all others.

ERIC K RIDEAL.

Our Bookshelf.

Atomtheorie in elementarer Darstellung. Von Prof. Dr. Arthur Haas. Pp. viii + 204 + 2 Tafeln. (Berlin und Leipzig: Walter de Gruyter und Co., 1924) 5·40 gold marks.

DR. HAAS is a gifted exponent, with a particular talent for compression. In this book of some two hundred pages he deals with the experimental establishment of the existence of the electron, the quantum theory of spectra, the modern work on X-rays and crystal structure, isotopes, and, in short, all that fascinating body of modern work which centres round the structure of the atom. He touches on such details as the selection principle of Sommerfeld and Landé, with its inner quantum number; the metastable state of the helium atom established by Franck; and the quantum theory of band spectra. There are, of course, only a few words devoted to each of such subjects, but these words are always pertinent and well chosen, and reveal the essence of the results obtained. Bohr's work of the last few years on the grouping of electrons in the general atom, and the interpretation of the periodic table in terms of quanta, is handled at comparative length, the periodicities revealed by the X-ray terms and the bearing of the spectra of potassium and calcium on the electron grouping in the first long period being well explained. The book concludes with an eight-page summary of its contents.

Dr Haas is particularly concerned with the quantum theory of optical spectra, and devotes comparatively little space to the work of Rutherford and his school on scattering and disintegration, and the work of Aston on isotopes, although, of course, this is not to say that these aspects are entirely neglected The general exposition is excellent, although the comprehensiveness of the scheme and the shortness of the book necessarily entail a certain abruptness For a reader already acquainted with some of the fundamental methods and results of the quantum theory, but yet not a specialist in this field, the book offers a very agreeable means of revising his knowledge and extending it in certain directions While the physicist will appreciate the review which the book affords, it is possible that the chemist and the layman, whom the author mentions in his preface, will find the simplicity which the lack of mathematics appears to lend to the book somewhat deceptive. The book has, however, many great merits: it is original in selection and arrangement of matter, concise in expression, includes very recent work, and is written with a knowledge and appreciation which are abundantly evident. E N. DA C. A.

Memoirs of the Geological Survey. Special Reports on the Mineral Resources of Great Britain. Vol 28. *Refractory Materials · Fireclays. Analyses and Physical Tests.* By F. R Ennos and Dr Alexander Scott. Pp. iv + 84 (Southampton Ordnance Survey Office, London: E Stanford, Ltd., 1924) 3s. net.

THIS report is intended to supplement volume 19, the well-known report on refractory materials Volume 28 contains notes on the mode of occurrence of fireclays; analyses of about 250 fireclays; and the results of tests on the refractoriness, porosity, tensile strength, and contraction of about 70 clays. The refractory tests for about 50 clays are applied to Ludwig's chart with very fair success To this it may be added that there is generally a difficulty in interpreting the fusion temperature of a fireclay No specification is able to give clear unequivocal instructions as to when a fireclay exhibits "signs of fusion." Discrepant results by different observers show that the "signs" are interpreted differently by different men. This also may explain some difficulties encountered in the general use of Ludwig's chart.

The novelty in the report is the statement that "probably the simplest and most useful chemical method of estimating the refractoriness of fireclays such as those investigated is to determine the combined water." The evidence plotted on p. 72 is far from convincing. From this it would be inferred that a fireclay with between 5½ and 12 per cent. of combined water would have a refractoriness of cone 28; or, taken from another angle, a clay with 5 per cent of combined water might have a refractoriness extending from cone 10 to 26! It will be necessary in the next edition to

show in what way the proposed novelty can be of any use whatever. It is claimed that the "report should prove to be a convenient work of reference in the brick-making and refractory-using industries" This claim will be abundantly justified, the Geological Survey is to be congratulated on the utility of these Special Reports. J. W. MELLOR.

The Pharmacists' Botany. By Dr. George B. Rigg. Pp. xvii+303. (New York: The Macmillan Company, 1924.) 16*s.* net.

MANY of the drugs in common use as medicines are derived from the vegetable kingdom, and are to a great extent supplied to the public by the pharmacist, who has to guarantee their identity and freedom from adulteration. For this reason the pharmacist is required to undergo an adequate training in the science of botany, for which a number of excellent text-books have been published, and institutes exist in which lectures and instruction in practical work are available Indeed, so large is the number of text-books that it is difficult to understand the necessity for an additional one unless it presents the subject in a manner specially adapted for a particular class of students. Prof. Rigg says that his aim has been "to include not only those phases of botany that are of specific use to the pharmacist, but also to give a general view of the subject which will serve as a background for him in his professional work."

A knowledge of the morphology and anatomy of the parts of plants used in medicine is particularly essential to the pharmacist, and in these respects a pharmacists' botany should give fairly complete, accurate, and precise information Prof. Rigg's book does not satisfy this condition; and inaccurate statements occur so frequently as to constitute a serious blemish. The book is well printed, and is illustrated by a number of photographs which, for the most part, answer the purpose for which they are employed. It cannot, however, be recommended for pharmaceutical students or pharmacists until it has been thoroughly revised, erroneous statements corrected, and the details more systematically arranged.

Penrose's Annual: the Process Year Book and Review of the Graphic Arts. Edited by Wm. Gamble. Vol. 27. Pp. xv+142+60+80 plates. (London: Percy Lund, Humphries and Co., Ltd., 1925.) 8*s.* net.

ALTHOUGH, as stated in the review of process work, there has been no outstanding achievement during the past year, the editor has provided a very pleasing and useful volume, as his custom is. The making of half-tone blocks seems to have arrived at a degree of perfection that it is very difficult even if possible to surpass, though the method may perhaps be simplified by the efforts made to render it more systematic. Rotary photogravure is being applied to multicolour printing, and the method is being successfully worked on sheet-fed machines producing excellent work up to speeds of 2500 copies per hour for each colour. A higher output may be expected from the same cylinders when rotary web machines are available. The replacement of the costly solid or tubular copper cylinders used for rotary gravure by iron cylinders faced with thin copper sheets has considerably advanced during the year.

The type used for the letterpress of the volume appears to be a modern reproduction of the Aldine type of the Hypnerotomachia Poliphili issued in 1499, concerning which there is an introductory article. The private press dealt with in an illustrated article is this year the Daniel Press owned by the late Rev. C. H. O. Daniel, of Oxford. Among the very numerous illustrations is a series of examples of posters, mostly in colours, twenty-four reproductions of the celebrated woodcuts of the 'sixties, many examples of offset printing and of colour work, all of which are excellent and of considerable technical interest, and some admirable also because of the beauty of the originals.

A Bibliography of Printed Maori to 1900. By Dr. H. W. Williams. (Dominion Museum Monograph, No. 7.) Pp. xvi+198. (Wellington, N.Z.: W. A. G. Skinner, 1924) n.p.

DR. WILLIAMS' bibliography of printed Maori publications contains nearly 1100 items The mere number, however, does not nearly represent the amount of labour which has been expended in its compilation, as each entry is annotated with information additional to the formal particulars, and in many cases some indication is given of the character of the contents. The author has departed from the strict rule followed by many bibliographers and has included items which he has not personally examined, but as such entries are indicated, those who use the bibliography will in these cases be on their guard. The entries are in chronological order —a disadvantage if the date of the book about which information is sought is not known, or if it is undated —but as the entries are naturally of a very miscellaneous character, ranging from Bibles and prayers to newspapers, dictionaries, and government documents, any satisfactory classification would be a matter of extreme difficulty. Further, the deficiency is to some extent made good by a very full index and a list of authors and translators. In the preface, Dr. Williams reviews previous attempts at Maori bibliography, and his introduction is a valuable account of Maori presses in which the work of the various missionary societies, both in reducing Maori to a written language and in printing it, is fully recognised. The first book to be printed in the language was "The New Zealander's First Book," by Thomas Kendall, the missionary (1815), for the instruction of the natives. It is, Mr. Williams says, scarcely to be recognised as Maori at all.

An Introduction to the Mathematical Analysis of Statistics. By Prof. C. H. Forsyth. Pp. viii+241. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1924.) 11*s.* 6*d.* net.

THIS work is intended primarily as a text-book for a course in mathematics and not as a reference book for the statistician. It is to be doubted, however, whether the mathematician as such will be quite satisfied with it. In its scope it is modest, commencing with useful chapters on numerical computation, finite differences, and interpolation, and proceeding by easy stages through probability, averages, a treatment of the normal frequency curve, to correlation. While there are copious and useful examples, the mathematical treatment is patchy and uneven; it is a useful, interesting, but unsatisfying production.

Letters to the Editor.

The Ages and Masses of the Stars.

SOME of the questions raised by Prof. Lindemann's interesting letter (NATURE, February 14, p. 229) can, I think, be answered at once out of our present store of astronomical knowledge

The sun radiates in round numbers two ergs per second for every gram of its mass, a total of 4×10^{33} ergs a second, of which $1{\cdot}7 \times 10^{24}$ ergs fall on the earth. If the earth had no other source of energy, it would radiate away $1{\cdot}7 \times 10^{24}$ ergs per second from its $5{\cdot}1 \times 10^{18}$ sq cm. of surface, and this would keep the surface at an average temperature of 276° abs. or 3° C This about accords with the facts If the earth's surface is not a perfect radiator the argument is slightly different but the final result is the same If, however, the earth generated energy at the rate of even a thousandth of an erg per second for each gram of its mass, it would have to radiate away $7{\cdot}7 \times 10^{24}$ ergs a second, requiring the quite inadmissible surface-temperature of 131° C. or more in so far as the earth's surface is not a perfect radiator. Even a generation of a 10,000th of an erg per gram per second, requiring a surface-temperature of 29° C or more, would seem to be out of the question

Clearly, then, the mechanism which produces the sun's radiation is absent from our earth, or at best acts very feebly under terrestrial conditions In giant stars, on the other hand, the mechanism is either more abundant or more potent As against the sun's radiation per gram per second of 2 ergs, the bright component of Capella radiates 30 ergs, α Orionis about 200 ergs, *V* Puppis over 300 ergs, and Canopus probably over 1000 ergs.

This leads on to Prof Lindemann's problem as to how the generation of energy per unit mass, E/M, depends on the temperature and density. I think the examples just given suffice to show that E/M is not a function either of the temperature or of the density, which is what ought *a priori* to be expected if the annihilation of matter is the source of energy. The energy transformed into radiation when an electron drops into a nucleus is about 0·003 erg, or a quantum of wave-length $6{\cdot}55 \times 10^{-14}$ cm, corresponding to a temperature of $1{\cdot}5 \times 10^{10}$ degrees. For the production of effects of this intensity, it is scarcely likely to make much difference whether the atomic temperature is 10^6 or 10^7 degrees.

The only satisfactory hypothesis I have been able to frame is that E/M in a star is a function of the state of development of the star. This hypothesis seems to fit all the facts; it would itself be explained if we could suppose matter as originally created to have consisted of a mixture of different types, some of which annihilated themselves rapidly, some only slowly, some perhaps not at all. As matter aged, the more destructible types would disappear, and the whole mass would in time consist only of the less destructible and non-destructible varieties. In a paper read at the January meeting of the Royal Astronomical Society, I showed that this supposition explains the observed facts of the giant-dwarf theory; indeed it seems almost to be demanded by these facts. We have to suppose that only the non-destructible or almost non-destructible varieties of matter are left on our earth, so that there must be kinds of matter in the sun and stars of which we have no knowledge.

The matter of which the earth is formed must, however, be of the same age as that of the sun. Whence, then, the enormous disparity in the two values of E/M? The only answer appears to be that the matter which formed the earth was not a fair sample of the solar substance. On any theory of its origin, the earth must have been formed from the outermost layers of the sun, so that we have to suppose the more destructible parts of the sun's substance to have been confined to its central regions, the heavier elements in the sun must have been more destructible than the light elements which were skimmed off to form the earth.

This leads to a consistent and comparatively simple scheme The heaviest element known on earth is uranium of atomic number 92, but no known reason compels the series of elements to stop abruptly at $N = 92$, and we may quite well suppose that in the sun there were, and still are, additional elements of higher atomic numbers. It is easily calculated that the nuclei of these elements cannot be entirely stripped of electrons, indeed the ionisation potential for the last electron in the uranium atom is about 230,000 volts, corresponding to a temperature of about 17×10^8 degrees (for resonance, 170,000 volts and 13×10^8 degrees) In elements heavier than uranium the quantum orbit $(\infty, 1)$ which approaches nearest to the nucleus comes so near as almost, if not quite, to touch. Even in uranium, as Rosseland has pointed out (NATURE, March 17, 1923), the distance of nearest approach is only $1{\cdot}5 \times 10^{-11}$ cm, which cannot be much greater than the radius of the uranium nucleus (cf. Neuburger, *Ann d Phys*, 70 (1923), p 145) Thus the atomic number 92 may well mark the division between atoms in which the electron orbits are all clear of the nucleus and those in which collisions, or at least very close encounters, between electrons and nucleus are possible The mechanism of annihilation of matter may be found in these collisions or close encounters between electrons and nucleus, in which case atoms of atomic number 92 and less may be immune. It should, however, be noticed that if the rate of annihilation is strictly independent of the temperature, the quantum orbit $(\infty, 1)$ cannot be involved, and annihilation must result from spontaneous drops from orbit 1 to orbit 0, as I originally suggested in NATURE (December 6, 1924) In any case we are free to suppose that matter as originally created consisted of elements of atomic numbers both above and below 92, but that electronic annihilation reduces the number of electrons in the heavier atoms until finally only atoms of atomic number 92 or less are left.

This brings us to a solution of Prof Lindemann's first problem to explain the existence of uranium on earth in view of its comparatively short half-life period of 6×10^9 years. Before the earth was born we imagine the heavier elements in the sun having their atomic numbers lowered by the annihilation of electrons, and emitting radiation in the process. A certain amount of uranium would be created out of the heavier elements by their degradation and probably also, as Prof. Lindemann suggests, a further (and much larger) amount out of the lighter elements by nuclear photosynthesis. The amount of uranium present in the sun would be determined by the condition that the total rate of creation should equal the rate of decay by ordinary radioactivity.

When the earth was formed out of the sun's uppermost layers, the creation of uranium would cease in the earth, for the supply of heavier elements would be cut off, as also the supply of radiation of high enough frequency to produce uranium photosynthetically. The earth's store of uranium would now gradually disappear by ordinary radioactive disintegration. But Prof. Lindemann's upper limit of 6×10^{11} years now appears merely as an upper limit

to the time since the earth was born out of the sun. By a more detailed but similar calculation Prof. H. N. Russell has estimated this upper limit at 3×10^{10} years (Proc Roy Soc., 99 A (1921), p 86).

Our hypotheses doubtless suffer from over-precision, and a more general discussion might permit of a greater age for the earth. It does not seem to me that the presence of uranium and thorium discloses any insoluble difficulties, although it would obviously have been more gratifying if the earth's age had come out a larger fraction of the estimated age of the sun

February 16.

Robert Browning as an Exponent of Research.

THE comment in NATURE of January 10, p 58, on poets who have touched the field of science may fitly be supplemented by some reference to Robert Browning, whose utterances in this field are often overlooked, although he has shown a deeper insight into the spirit of research than any other poet known to me, and has expressed it many times in glowing words This trait is the more remarkable since Browning evidently knew little and cared little about the particulars of science, and probably found them somewhat repellent, being in this respect widely different from Tennyson, who was well versed in the scientific literature of his day, and used his knowledge of it freely Yet Tennyson's attitude remained always that of the orthodox cultured "naturalist" of Victorian times, skilful in observation, but recoiling in alarm from the outlook to which observation led Browning on the other hand took little heed of the path, but pressed on boldly toward the outlook and gauged the qualities required to reach it. Even in his conception of a poet, as expressed in "How it Strikes a Contemporary," he sees an investigator pure and simple, with an aptitude for understanding and recording vividly pictured in the person of the elderly man of Valladolid, the true "Corregidor" of the city, whose

"—very serviceable suit of black
Was courtly once and conscientious still",

who

"—walked and tapped the pavement with his cane,
Scenting the world, looking it full in face",

everywhere taking such keen "cognisance of men and things" that you might even

"—surprise the ferrel of his stick
Trying the mortar's temper 'tween the chinks
Of some new shop a-building—."

The most frequently quoted though scarcely the most cogent expression by Browning of the spirit of research is contained in that noble threnody "A Grammarian's Funeral," which ought by now to have drawn from some great composer a stately "Searcher's Funeral March" It is unnecessary to recall the many familiar passages—the whole poem is an emotional rendering of delight in the pursuit of knowledge, and pride in its acquisition, whether the apparent gain be great or small.

"He settled *Hoti's* business—let it be!—
Properly based *Oun*—
Gave us the doctrine of the enclitic *De*"

—achievement enough for a Hymn of Triumph

Browning's power in the field of psychology has always been recognised, though his psychology is, of course, tinged deeply with emotion, as in that celebrated and much-discussed example "The Ring and the Book" His grip of the scientific mentality is perhaps nowhere better displayed than in his subtle analysis of the mind of an investigator confronted with a supernormal phenomenon, given under the guise of "An Epistle," from Karshish, the vagrant Arab physician—

"—the picker-up of learning's crumbs,
The not-incurious in God's handiwork,"

to his Sage at home—

"To Abib, all-sagacious in our art,
Breeder in me of what poor skill I boast."

Antique in form but modern in application, the "Epistle" reveals the imagined writer as the possessor of exactly the mental qualities which would do credit to a young travelling medical man of the present day.

This appreciation of research is not, however, noticeable in Browning's earlier poems, one searches vainly for any clear expression of it in "Paracelsus," where one might expect to find it, but it crops up again and again, with increasing intensity, in his later work, and often in unexpected places. Take this, for example, from "Apollo and the Fates":—

"—'Tis Man's to explore
Up and down, inch by inch, with the taper his reason:
No torch, it suffices—held deftly and straight.
Eyes, purblind at first, feel their way in due season,
Accept good with bad, till unseemly debate
Turns concord—."

Or this, again, from "Fust and his Friends":—

"—Man Ignores—thanks to Thee
Who madest him know, but—in knowing—begin
To know still new vastness of knowledge must be
Outside him—to enter, to traverse, in fee
Have and hold! 'Oh, Man's ignorance!' hear the fool whine!
How were it, for better or worse, didst thou grunt
Contented with sapience—the lot of the swine
Who knows he was born for just truffles to hunt?—
Monk's Paradise—'*Semper sint res uti sunt!*'
No, Man's the prerogative—knowledge once gained—
To ignore,—find new knowledge to press for, to swerve
In pursuit of, no, not for a moment attained—
Why, onward through ignorance! Dare and deserve!
As still to its asymptote speedeth the curve,
So approximates Man—Thee, who, reachable not . . ."

Is it not by glowing rhapsody of this kind, rather than by the rendering in verse of specific results in science, be it ever so skilfully and accurately, that the poet can best touch the imagination with a sense of what science is, and may be? G. W. LAMPLUGH.

St. Albans, January 31

The Origin of Sponge-Spicules.

IN the preliminary account by my friend Prof. Dendy (NATURE, February 7, p. 190) it is difficult to see evidence for the independent organic life of his "scleroplastids" There is nothing to prove this hypothesis in the observation that the first rudiment of the spicule in Stelletta is a skeleton-crystal on the tetrahedral system, afterwards overlaid (as we have long known in the tetracrepid desma of Lithistida) with siliceous deposit in amorphous aggregation. Obviously twinning and repetition of branches (also long known) are not arguments against the crystalline character of form in spicules. In 1898 I pointed out certain resemblances to the relations between a symbiotic organism and its host in the relations between a crystal, utilised as a spicule, and the sponge which has secreted it (Proc. Roy. Soc., vol. 64, p. 71). These resemblances seem to have misled Prof. Dendy to his new theory, but he adduces no facts which give evidence for separate organic life in the spicule, or impeach the evidence for its crystalline structure.

I advocated crystallographic explanation of their

symmetry for siliceous as well as for calcareous spicules (*l.c.* p. 70), and the brusque reply then often given that "opal is a colloid" would scarcely now be tendered. Minchin, who at that time followed Schulze in thinking the form of spicules a result merely of the geometry of the canal-system, later accepted the crystallographic theory for calcareous and hexactinellid spicules, though not for those of Demospongiæ (1905, *Zool Anz*; 1908, *Q.J.M.S.*; 1909, *Ergebn. u. Fortschr. Zool.*, ii. pp. 251, 265).

Later work on suberitids, and on the sponge the name of which Prof Dendy has strangely changed to Donatia, has convinced me that the case is as strong for these sponges as for the hexactinellids The Suberitidæ, though included by Prof Dendy in his hospitable group of Tetraxonida, have triaxon spicules; while Donatia shows very interesting evidence of tetraxon crystallisation The conjecture is possible that crystallisation takes place on the tetrahedral system when the spicopal contains 6 per cent of water in chemical union (Siphonidium, Sollas, 1888; Geodia, Butschli (Jannasch) 1901) and on the cubic system when it contains 7 per cent of water (Suberites, Sollas, 1888, Polopogon, Schulze (Moly) 1887), which might be complementary (cf Sollas) to $(SiO_2)_6$ and $(SiO_2)_4$ respectively

I welcome in paragraph (1) [second series of numbers] the word "Mendelian" as showing that our foremost systematist recognises now that the sponges which he investigates are not guaranteed to be thoroughbred Classifiers in general have taken too little account of the *prima facie* promiscuity of the ocean, and for the innumerable "species" of sponges which infest our books "hybridisation must play great part in the characters we laboriously tabulate" (Bidder, Journ. Linn Soc., vol 34, p. 302) If Prof. Dendy will recognise also that the existence and character of spicule-forms can be modified in the individual as the direct physiological consequence of changes in the chemical constituents of sea-water, in temperature, or in light, the nomenclature in his admirable monographs may become simpler

As regards the independent genesis of spicules, the last sentence of Prof. Dendy's letter indicates that he has not observed "scleroplastids" outside cells, and I cannot see that the remainder offers any evidence that they originate outside cells, though I know no reason against silica being deposited in the interstitial jelly of sponges, as lime is in vertebrate cartilage Physiologists have not thought it necessary to suggest that we should recognise as symbiotic bacteria the calcareous granules in the ground-substance of cartilage, or in other tissues the crystals of urate of soda "which are at first gelatinous, but become crystalline" (Noel Paton, Enc Brit., 18, 137) like Prof. Dendy's "scleroplastids."

GEO. P. BIDDER.

Cambridge, February 14.

Instability of Viscous Fluid Motion.

By the courtesy of Mr. C. S. Elton, Dept of Zoology, University Museum, Oxford, the writer has seen photographs taken at Spitsbergen of loose stones on mud flats forming striking patterns of polygons. On inspecting these photographs, Capt. D. Brunt of the Meteorological Office at once recalled a paper by Rayleigh "On Convection Currents in a Horizontal Layer of Fluid" (*Phil. Mag.* 1916). The present writer in turn recalled Bénard's thesis on the same subject (Gauthiers-Villars, Paris 1901).

On referring to these papers, it was found that Rayleigh in fact gives an approximate mathematical theory of Bénard's experimental work, and shows that where a vertical flow of heat produces a temperature and density gradient in a horizontal layer of fluid, an apparently unstable arrangement, with greater density above, acted on by gravity, may actually be stable until the relation is satisfied,

$$\rho_2 - \rho_1/\rho_1 > 27\pi^4\kappa\nu/4gh^3,$$

where ρ, κ, ν, h are the density, conductivity, viscosity and depth.

Multiplying both sides by $gh\rho_1/6$ and dropping the suffix to denote that the mean density may be taken, we get,

$$gh(\rho_2 - \rho_1)/6 > 27\pi^4\kappa\nu\rho/24h^2.$$

The expression on the left-hand side is the energy released by inverting the fluid so that the density gradient downward is the same as the original gradient upward. This expression may be used as an approximation even when the gradient is not linear

When the critical gradient upward is exceeded, instability must appear, at first in a chaotic manner; but certain modes of motion have greater rates of increment characterised by the (real positive) value of q in the factor $\exp(qt)$, and these modes finally prevail over all others.

When the bottom boundary is a solid surface, and the upper boundary a free surface, the chance centres of instability seem always to form on the solid boundary, and to send up threads of fluid vertically which reach the surface and there spread out on all sides until they meet the neighbouring outward flows These meetings determine boundary sheets also vertical or nearly so, down which return flow takes place, the circulation being completed along the bottom

Polygonal prisms are thus formed in each of which circulation takes place The number of sides may be 3, 4, 5, 6, or 7 The triangles are rapidly crushed out of existence, the squares follow more slowly, and if the conditions are kept sufficiently uniform, hexagons finally cover the whole surface with great regularity of form and size

If, however, there is a general flow, v, across the plane, the vertical threads are drawn out into vertical sheets parallel to the v-flow. The return flow also takes place downwards along vertical sheets parallel to the former These sheets divide the layer into long compartments of rectangular cross section

The problem becomes two dimensional, and the motion of instability takes the form of u-w flow in closed paths within the compartments formed by the sheets The most vigorous mode is with the distance between adjacent sheets, one rising, one descending, equal to the depth

When the v-flow comes to rest, cross divisions appear forming squares on the surface, the most vigorous mode for squares being with side $2\sqrt{2}$ times the depth according to the theory, but before there is any sign of this being reached the squares give way to the more vigorous hexagonal mode There is no mathematical solution available for the hexagon, but we may infer from experiment that when the mean diameter is from three to four times the depth, the hexagonal mode is more vigorous than all others.

In applying these results to the stone polygons on mud flats, it may be remarked that the ground, deeply frozen in winter, thaws superficially in summer to a depth varying from a few centimetres upwards. The frozen surface beneath is called the ground ice, and is at 0° C. in the absence of salt water The density of the water will therefore increase upwards with temperature until 4° C. is reached. When we consider the solid matter in suspension, the mixture will have complicated properties in respect of proportion of water, mean effective density, conductivity, specific heat and viscosity, and attempts to form a quantitative estimate of the condition of instability

meet with a formidable array of unknown quantities. According to the theory, however, only a trivial gradient is required for depths exceeding a decimetre to produce instability, and slowly it may be, but in the long run inevitably, the water must circulate, sorting out the lighter materials and conveying them to the polygonal boundaries of the downward flow.

On these assumptions the following predictions were made:

(*a*) That the surface would not depart much from the temperature of maximum water density, 4° C.

(*b*) That in the absence of stones which were merely indicators of the motion, polygonal marks would be formed on the mud.

(*c*) That where the mud flowed down gentle slopes, lines of stones would be formed parallel to the flow, but that where the mud came to rest, cross divisions would appear forming rectangular divisions which would give place later to polygons

(*d*) That the diameters of the polygons would be from three to four times the depth

(*a*), (*b*) and (*c*) were confirmed by Mr Elton, and (*d*) was in accordance with rough observation, the depth being about a metre, the mean diameters about three or four metres

Mr. Elton has since written that according to B. Högbom, from whose paper "Ueber die geologische Bedeutung des Frostes" (*Bull. d geol. Inst Upsala*, vol. xii 1914), the illustration (Fig 1) is reproduced, an explanation based on Bénard's work was put forward by Otto Nordenskiold in "Die Polarwelt und ihre Nachbarlaender" (Leipsig und Berlin, 1910), but was withdrawn in a paper in the "Wiss. Ergebn. d. Schwedische Sudpolarexpedition." 1911. Mr. Elton also gathers from a paper by Huxley that Eakin (U.S.A. Geological Survey Bulletin, No. 631, 1916) has proposed a similar explanation.

FIG 1.—Stone Polygons on Erdmann's Tundra, Icefjord, Spitsbergen.

On applying an arithmetical comparison between Rayleigh's criterion and Bénard's experiments, it appears that instability sets in with less than one-tenth of the gradient required by theory. The fluid used was melted spermaceti, for which the viscosity and conductivity are not known, and for this and other reasons connected with the mounting of the experiments, the comparison is not satisfactory.

Of more general interest is the application of the criterion to the atmosphere. Using the value of $\kappa = 5\nu/2$, given by the kinetic theory of gases and assumed by Rayleigh, the following table of temperature departures from the adiabatic lapse of neutral equilibrium is obtained:

Depth of layer	1 cm.	1 m.	100 m.
Temperature difference in excess of adiabatic	9° C.	9° C. × 10^{-6}	9° C. × 10^{-12}

To account for observed stable layers in the atmosphere with a lapse rate far exceeding the adiabatic for many metres, it is necessary to look for an effective conductivity far exceeding the slow diffusion of the kinetic theory, and this may possibly be found in radiation and absorption, which account for the transfer of heat on an immensely greater scale. Convection of heat is excluded by the assumption of stability.

Even if stability breaks down almost instantaneously, the modes of instability will still be controlled by the considerations discussed above, but further comment must be left to meterologists.

It is remarkable that an analogous criterion may be extended to Prof. G. I Taylor's experiments on the stability of fluid motion between coaxial circular cylinders rotating with given angular velocities ω_1, ω_2. If r is the radius, $\omega r = v$ the velocity perpendicular to radius and axis, then the equilibrium of a perfect fluid rotating steadily about the axis is stable, neutral, or unstable as vr increases, is constant or decreases radially outwards.

If a particular value of vr were an inherent permanent property of each element, the same statement would be true for a viscous fluid. But just as the density gradient in Bénard's experiment is due to the flow of heat, so here the vr gradient is due to the diffusion of v according to the relations for heat transmission, from the faster moving cylinder to the other.

Both the two dimensional case above and Taylor's case come under Rayleigh's extension of Helmholtz's theorem of minimum dissipation, so that the steady dissipation due to the not necessarily small v-motion, and the additional dissipation due to the small u-w motion are independent. Thus we have merely to replace $\kappa\nu$ by ν^2 and the analogy is applicable at once.

Rayleigh has pointed out that with two fixed solid boundaries, the effect of viscosity in increasing the dissipation will be increased In the simple case of laminar motion v across a plane with one free surface, the dissipation is increased four times, for the same mean v, when a second fixed surface takes the place of the free surface.

Taking this as an approximation to the effect in the more complex case of u-w circulation, the criterion becomes .

Energy released by inverting the vr gradient radially $> 27\pi^4\nu^2\rho/6h^2$, *i.e.* four times the previous value.

In this form the boundary line between stability and instability in the ω_1, ω_2 plane is found to be a hyperbola in accordance with Taylor's result, and the diameter is given with an accuracy which is perhaps a trifle fortuitous.

So far this holds only when ω_1, ω_2 have the same sign. When they are of opposite signs, nodes may appear in the u-w circulation, and it becomes necessary to introduce terms of the form $\sin(2\pi z/h)$ as well as of the form $\sin(\pi z/h)$ corresponding to the gravest mode of instability which alone Rayleigh considered.

Enough has been done to allow the analogy between the two-dimensional case worked out by Rayleigh, and Taylor's case to be drawn in full detail.

There are many applications of the criterion which suggest themselves, and seem to make it worth while to bring forward this provisional discussion for wider consideration.

A. R. Low.

The Library, Air Ministry,
London, December 29.

THE experiments of Bénard, and the theoretical discussion by the late Lord Rayleigh, referred to by Major Low, deserve careful consideration from the point of view of their application in meteorology. Rayleigh showed that a layer of fluid can remain

stable, even with the denser fluid above, in virtue of its conduction and viscosity. In the atmosphere it is customary to regard stability as associated with a fall of temperature with height limited by the adiabatic lapse-rate, 1° C per 100 metres for dry air, a greater lapse-rate, or fall of temperature with height, denoting instability. It is, however, an accepted fact that lapse-rates greatly in excess of this value are of frequent occurrence, especially in the lowest 10 or 20 metres, at which height they can be observed at some time of day on almost any day of the year.

An analogy with Rayleigh's result suggests that these large lapse-rates are able to exist only in virtue of the viscosity and conduction of the air When, however, we put figures into Rayleigh's formula, we find that in a layer 10 metres thick, the lapse-rate could not exceed the adiabatic by more than a very minute fraction But Rayleigh's treatment only deals with conduction in the strict sense, the coefficient of conduction for air being derived theoretically from the kinetic theory of gases Now in air the transfer of heat by radiation is enormously greater than by molecular conduction, and for air we should therefore use some higher factor than the ordinary coefficient of conductivity κ in Rayleigh's formula An attempt is being made to derive an expression corresponding to that of Rayleigh for a compressible fluid, taking into account the various factors outlined above.

When we come to discuss the form of circulation which enters when the equilibrium breaks down, we find several examples in meteorology. The cellular form in which the breakdown of the unstable arrangement takes place is most clearly shown in mammato-cumulus clouds. A very fine example of this type of cloud is shown in a photograph by Dr W. J S. Lockyer, reproduced in NATURE for November 17, 1923, p 725 This type of cloud was further discussed by Dr. G. C Simpson in NATURE for January 19, 1924, p 82. Such clouds occur usually in the rear of thunderstorms where there is a general slow settling of air. If there is in this region a layer of cloud or damp air, with a layer of dry air beneath it, then, as pointed out by Dr Simpson, in consequence of the descent the dry air is warmed adiabatically at a higher rate than the damp air, and instability results. The small cloudlets are comparable with the polygonal prismatic compartments of Bénard's experiments.

There is one possible difference, in that in Bénard's experiments the lower boundary of the fluid is a solid surface, and the circulation in each compartment is upward at the centre. In the case of the unstable layer which forms the mammato cloud, the boundaries above and below are interfluid surfaces, and it is possible that the circulation in the individual cell is in the reverse sense to that of Bénard. There is no obvious criterion for determining this. It may be a question of which sense of circulation gives the smaller dissipation of energy. The analogy with Bénard's cells would require that the instability should extend through a layer the depth of which is determined by the physical constants, and is relatively shallow.

It is possible also that some of the phenomena associated with thunderstorms can be explained in the same way. Thunderstorms may be ascribed to vertical instability in the atmosphere, and the violence of thunderstorms would appear to indicate that a high degree of instability is built up before the breakdown occurs. It is suggested that this is brought about by the stabilising effect of transfer of heat and viscosity, up to a critical stage, beyond which the arrangement is unstable, and breaks down with violence. The analogy with Bénard's experiments is borne out by the frequent occurrence of a network of thunderstorms, which break out at the same time over a wide area Further, the ratio of horizontal to the vertical dimensions of thunderstorms is of the order suggested by the analogy with Bénard's cells.

The form in which the instability breaks down near the ground, in the frequent superadiabatic lapse-rates which occur in the bottom layer of the atmosphere, affords an interesting problem, but as this problem is under investigation by others, it can only be referred to in passing Certain details of the records shown by the microbarograph can probably be explained in this manner D BRUNT.

Meteorological Office,
Air Ministry, Kingsway, W C 2.

Blood Pressure in Early Life.

IN a friendly review of my work on "Blood Pressure in Early Life" appearing in NATURE of January 10, criticism is directed to a deduction I made on pp 50-51 regarding the average expenditure of work by the heart in maintaining the circulation at different ages Though this was only one of the sixteen main conclusions, and I admitted it to be the most doubtful of them, I should be glad to have the opportunity of replying to the points which are raised.

I intended to make it clear that my argument regarding the proportionality between cardiac energy expended per minute and the product of pulse pressure and pulse rate was limited to a comparison between *mean values* for large groups of individuals of the same age, that there is any basis for thinking that such a relation necessarily holds good in comparing one individual with another I did not suggest. The initial assumption was that energy expended by the heart was approximately proportional to volume of systole × pulse pressure × pulse rate I then stated (p 50) that "the value of V (volume of systole) cannot be measured readily and it is no doubt variable within certain limits in individuals of the same age, weight, and height, but we may perhaps make two assumptions. (1) that during the period of growth the mean values of V for large groups of growing individuals are directly proportional to the mean body weights of these groups; (2) that the average value of V remains fairly constant in adults up to middle life" From assumption (2) plus the original one it followed that "in comparing large groups of young adults aged 20 and upwards of the same sex, the *mean* product of pulse rate and pulse pressure is directly proportional to the *mean* work done by the heart per minute." This deduction is not merely one of my original assumptions, as the review states, since we have got rid of V from the original equation From assumption (1) plus the original one I further deduced that the "mean expenditure of cardiac energy per minute for a group of individuals of a given age" is proportional to mean weight at that age × mean value of product of pulse pressure and pulse rate for that age. The word "mean" was monotonously repeated and also emphasised by italics because the application of the same reasoning to a comparison between individuals would be unsound, since there is every reason to suppose that V is as variable amongst individuals of a given age as any other anthropometric factor, and probably more variable than most factors.

Without disparaging experiments on the isolated mammalian heart, I should have grave doubts whether the complex conditions met with in the human subject could be reproduced with sufficient certainty to pronounce for or against the truth of any of these

assumptions or deductions Even granting that they could, if the pulse-pressure × pulse-rate product is made to vary in the same heart by artificial means, other factors may come into play, and I know no evidence to suggest that the equation would hold good under any but normal conditions, on the other hand, if only a few different hearts are compared under constant conditions, we are not dealing with mean values but with individuals

The real point at issue is whether the pulse pressure is a factor at all in the actual work done. I cannot agree to the contention that the energy expended "is in no direct manner connected with the pulse pressure" It seems reasonable, however, that the mean pressure should also be taken into account In the somewhat analogous problem of a pump working against gravity, the work done per "beat," ignoring the kinetic factor, is proportional to cross-section of pipe × mean height of fluid × change in level of fluid, and if the fluid level be restored to its original height by a siphon before the next beat, a further multiplication by number of beats per minute gives an expression for energy output per minute Applying the analogy to the circulation, the mean cross-section of the arterial system at ages during growth may be assumed to vary as the mean cross-section of the body, or as the mean square of a linear measurement such as the stature at those ages, and the other factors in the expression are represented by mean blood pressure, pulse pressure, and pulse rate The values of the fourfold product at ages from 10 to 21 (using smoothed figures from the curves and dividing the results throughout by 10^6) are —

10. 4466	13. 6863.	16. 11,264.	19 10,992.
11. 5075.	14. 8155.	17. 11,765.	20. 10,670.
12. 5861.	15. 9927.	18 11,465.	21. 10,490.

This method leads therefore to precisely the same conclusion as before, namely, that "when the age of 16 has been reached the average heart is performing as much or more gross work per minute than in adult life in spite of the fact that it has presumably not attained full size"; the maximum, as before, occurs about 17. PERCY STOCKS.

Dept. of Applied Statistics,
University College,
London, January 26

I REALISE that Dr Stocks, when making his initial assumption that the energy expended by the heart per minute was proportional to the product of the volume of blood expelled at each systole, the number of beats per minute and the pulse pressure, intended this assumption to apply merely to the relationship of the mean values of these factors in large groups of individuals I do not see, however, how this makes the assumption any the more justifiable. The real point at issue is, as Dr Stocks himself mentions in his letter, whether the pulse pressure is a factor in the expression for work done

In the "somewhat analogous problem of a pump working against gravity," the work done per beat is admittedly proportional to the product of the capacity and intensity factors, namely, cross-section of pipe × change in level of fluid and the mean height of the fluid respectively In the case of the heart the pulse pressure, if it is of any significance as an indication of energy expenditure, must be shown to be related to either the capacity or the intensity factor of this energy. There seems to be no justification for including it in the former, especially since the mean output per beat for large groups of growing individuals is assumed to vary directly as the mean body weight. Similarly, to include it in the latter seems equally unjustifiable, seeing that the intensity factor in cardiac work, as was pointed out in the review, is the mean blood pressure during the ejection phase of systole Accurately to determine this mean it would, of course, be necessary to know the average time course and to take the integral of this. This is, however, impossible in man, but the true figure may be approximated to sufficiently accurately if we take in its stead the mean between systolic and diastolic pressures.

If this is done and the product of body weight and mean pressure between the systolic and diastolic levels determined for different age groups, it will be clear that the figures do *not* show any maximum at the age of 16 or 17 years. One may conclude from this that at no period during adolescence is the average heart performing as much work per beat, or taking pulse rate into consideration, per minute, as in adult life. THE REVIEWER.

Diamagnetic Orientation.

GLASER, in a recent paper (*Ann. der Phys.*, 21, 459, 1924), of which a short account was given in NATURE, January 10, p. 64, has shown that the apparent molecular diamagnetic susceptibilities of H_2, N_2 and CO_2 are three times as great at low as at ordinary pressures. He attributes this to orientation, the tendency to orientate being counteracted at higher pressures by the effects of molecular collisions. He is unable, however, to account for the factor 3 in this way.

If the molecules tend to orientate with their axes along the direction of the field, this factor may be easily accounted for. Owing to the relatively large mass of the nuclei, it is only about the line joining them that the molecule will acquire an appreciable magnetic moment under the influence of the field, the effective field being the component of the external field along the direction of this axis. The ratio of the apparent susceptibility for fully orientated molecules to that for molecules orientated at random will then be $1/\int_0^{\pi/2} \cos^2\theta \sin\theta d\theta = 3$.

The importance of extending the measurements to monatomic gases need scarcely be emphasised.

Animal Mechanism.

WHEN a swan is rushing to the attack of an adversary, the head is lowered and the neck is protended almost horizontally. I had always associated this posture with mere anger, but, during the excessive Thames floods of last December, when swans could often be seen striving against the stream, sometimes, so far as could be judged, in the apathetic state of desperate exhaustion, the same pronation of the neck was frequently evident.

The explanation seems to be dynamical, for the reactions on the feet of the bird would, without the counterpoising action of the neck, tend to rotate the body about a horizontal axis, head backwards. Air resistance also plays a part.

It is of interest to note that the racing motor-cyclist, in his unreasoned but experimentally justified preference for forward weight, has found a solution akin to that of the swan. Many sprinters, especially when starting, use the same principle.

The Skull and Ancestry of Robert the Bruce.

WE know men better when we have seen them in the flesh, even if we have no speech with them. A knowledge of their homes fills out our mental picture of them. Darwin becomes more alive to us when we have been round his home at Down. There have always been a few who cherish the belief that the skulls of our famous dead, the homes in which their brains lived, and the bony screens on which their living visages were spread, can speak with a precision and with an intimacy beyond even the efforts of the best artist. For the human skull has a language of its own; one which is hard to decipher. After centuries of endeavour we can construe only its simpler hieroglyphics; yet we do continue to improve, and our progress justifies the belief that the day will arrive when a rational craniology will become the handmaid of biography. This is the belief of Prof. Karl Pearson; in a monograph he has published on "the skull of Robert the Bruce, King of Scotland," he has written thus:

"I can imagine a time, when public opinion being sufficiently educated, it shall be looked upon not as a desecration but as a solemn duty, reverently to exhume and study the crania of the departed great with a view of adequately correcting portraiture, or of supplying it where it is deficient." [1]

As all good Scotsmen know, Robert the Bruce was born in 1274 and died in 1329, aged fifty-five. He was buried in Dunfermline Abbey, and there his bones lay until 1819, when they were uncovered during certain rebuilding operations. The traditional and circumstantial evidence leave little if any doubt that the skull and skeleton found were those of the great king. Accurate moulds of the skull were taken before it was reburied; a cast taken from this mould is in the Museum of the Royal College of Surgeons, England, where it is placed cheek by jowl with a King Robert of a later date—Robert Burns. Another and, in Prof. Pearson's estimation, a better cast of Bruce's skull is preserved in the Museum of Edinburgh University, and it is this which he has made the subject of his monograph.

The writer of this notice has also made a study of the cranial cast of the Bruce,[2] and although his methods differ from those employed by Prof. Pearson, yet the main conclusions reached by each are in agreement. The skull of the Bruce has characters of the most outstanding kind, chief of which are the rugged robustness of its face, the outstanding ridges over the eyes, the enormous width across the face from jowl to jowl, and the strength of jaws. He was bull-necked, as is plainly indicated by the extent and strength of the bony platform on the base of the skull whereto the neck is fixed. Such an extensive platform signifies large and strong muscles in the neck, and such muscles in the neck require equally strong muscles of the spine and body. There is in the Museum of the Royal College of Surgeons a rib of King Robert; it is the 9th of the left side. It had been broken in some mischance which had befallen the King, but had healed well and soundly.[3] The rib shows him to have been a big-chested man, one we should expect to have a relatively long body; and yet his thigh and leg bones were not long. Prof. Pearson finds that their dimensions answer to those of a man about 5 ft. 6 in. in height. Bruce may well have been one of those men who seem tall when seated and yet of medium height when standing up, in which case we may add two or three inches to the estimate given by Prof. Pearson.

Bruce's skull is long and particularly wide—its width being about 78 per cent. of its length. His brain was large, Prof. Pearson estimates his cranial capacity to have been 1595 c.c.—about 8 per cent. above that of the average Briton. Neither Prof. Pearson nor the writer attach importance to the size of the brain; what has impressed both are the massiveness and strength of the cranium itself. "Bruce's skull," writes Prof. Pearson, "suggests a man of most exceptional muscularity and strength, with a bull-neck and ardent passions." The writer has expressed his conclusions thus: "It would be the strength and configuration of the face rather than the size of the brain that would weigh with most students if they sought to hazard a guess as to the nature of the man of whom such a skull had formed part. We should suppose him to have been a forceful leader of men." [4] Herein Prof. Pearson and the writer are drawing their inferences not from any systematised body of knowledge but from the everyday observation open to all—that men with such cranial characters as we find in Bruce are swayed by the strong appetites and passions of the natural man. If tradition speaks true, Bruce was no exception to this widely held belief.

Of what race was Bruce? Prof Pearson, following tradition, looks upon him as a hybrid between Norseman and Celt, and adds: "He was able by Celtic imagination, with a certain dash of slimness, to win the Scottish nation to his side, and by aid of Nordic physique and persistency to be triumphant over his enemies" This statement might well be a quotation from the speech of a political historian; it certainly is not the language of craniology. The term Celt has been applied to diverse breeds of men, but Bruce's cranial type is not prevalent in any of them. Nor is it a type which is found in Saxon or Danish graveyards, although samples do occur in the Frankish burials of the north and west of France. Bruce's skull has more in common with what has been named by British anthropologists in recent years the "beaker" type than with any other known to the writer. Men with this type of skull began to take up their habitation along the eastern coasts of Britain early in the second millennium B.C. They are known as "beaker" men because of the peculiar kind of earthenware vessel buried with them. Before they appeared in Britain they had penetrated to Baltic lands and spread southwards into France. Bruce's ancestry may have acquired the "beaker" blood in Baltic lands, in France or in Cleveland, where the type still persists.[5]

It is this persistence of type which lends interest to the comparison of ancient and modern skulls. Those familiar with the skulls of beaker men obtained from

[2] Phrenological Studies of the Skull and Brain cast of Sir Thomas Browne of Norwich, Henderson Trust Lectures, No. III. Edinburgh, 1924.
[3] This rib was taken from the open tomb in 1819 by Dr. William Mackenzie, whose life appears in the "Dictionary of National Biography." He died in 1868. He was both accurate and learned, and was regarded in his day as the leading ophthalmic surgeon in Scotland.
[4] *Loc. cit.*
[5] The spread of the "beaker" type has been discussed in an address given by the writer on "The Bronze-Age Invaders of Britain," Journ. Roy. Anthrop. Institut., 1925, vol. 45, p. 12.

the round barrows of Wilts have no difficulty in recognising their counterparts among their companions of to-day. After a hundred matings or more in a land where long heads have vastly outnumbered the round heads, this beaker type still persists. Darwin was almost a representative "beaker" man, wherever leading British men are met together there is certain to be an undue proportion of round-heads In more senses than one the beaker type is dominant.

The first article[6] in the number of *Biometrika* which contains Prof. Pearson's study of the Bruce's skull, helps us to understand such a persistance of a human type. This article by Dr. Ernest Warren deals not with human beings but with foxgloves, but we can legitimately transfer his results from the one to the other, for we have every reason to believe that heredity works in the human stirp just as it does on that of the foxglove Dr. Warren observed that parental characters may form a perfect blend in the progeny, or there may be no blending—the characters of one parent dominating or ousting the corresponding character of the other parent To use his own words: "Mendelian inheritance and perfect blending inheritance may be regarded as the two end terms of a series, and all grades of partial blending or partial segregation lie between." The same must be true of human matings, at least such a supposition accounts for the facts which are brought daily to the notice of anthropologists The man of the Magdalenian period, unearthed recently near Bonn, had just such a development of cheek and jaw as reappeared in Robert Bruce some ten or eleven thousand years later.

In his search for authentic portraiture of the Scottish king, Prof Pearson consulted the image on the Scottish coins of Bruce's reign He found that the stamped image was in no sense a portrait. "As for the eye," writes Prof Pearson, "it is remote from the orbit, but this is an artistic (?) convention even in the case of modern designers' profile portraits. On a penny postage stamp or a half-crown of his present Majesty the King, the distance from nasion to outer border of orbit is about one-third of the distance from the nasion to auricular passage, whereas in the profile of a skull it is nearer one-fifth" Herein Prof Pearson does the designer of His Majesty's image a certain degree of injustice. The extent to which the nasion (or root of the nose) projects in front of the side wall of the orbit, when a skull is viewed in true profile, is a guide to race, and hence the writer has given this facial character some attention. In Bruce's skull the nasion lies 97 mm in advance of the mid-point of the ear passages; the sides of his orbits 72 mm.; the difference between these measurements—the *naso-orbital depth*—is 25 mm., this being 25·8 per cent. or rather more than a fourth of the auriculo-nasal projection.

Herein King Robert was typically British, for in ten male British skulls taken at random, the mean of the corresponding measurements were 95·8 mm. and 71·2 mm.—the naso-orbital depth being 24·6 mm.—or 25·7 per cent. of the naso-auricular line. To obtain a face in which the naso-orbital depth falls to Prof. Pearson's standard, a fifth or 20 per cent., one has to go to skulls of Chinamen. Ten male skulls of this race, taken at random, gave these measurements, 92·8 mm. and 74·4 mm.—the naso-orbital depth being 18·4 mm.—almost exactly one-fifth of the naso-auricular projection. In the image on the half-crown which lies before the writer, the nasion is 8 mm. distant from the ear passage and the margin of the orbit 5 mm. The naso-orbital depth given by the designer of the coin is 38·5 per cent. of the naso-auricular distance—certainly 12 per cent. more than it should be were His Majesty's head represented in true profile But then it is not a true profile; the artist has purposely turned the head far enough towards him to make the opposite (right) eye-brow visible, and his drawing gives His Majesty's features in their just position It is otherwise with the photographs which Prof. Pearson has reproduced of the Bruce's skull; the camera, as cameras always do, has given a distorted view of the skull, reducing Bruce's naso-orbital distance to one-fifth of the naso-auricular line, thereby committing an error of nearly 6 per cent The photograph of a skull cannot take the place of an accurate drawing; in the writer's opinion, photographs are useless as craniological documents

It is a curious circumstance that although Scotland has produced an undue share of anatomists, she has had to depend, until lately, on Englishmen for a knowledge of her own people It was Dr John Beddoe who made the first anthropological survey of Scotland; it was Sir William Turner who first made a study of the craniology of its inhabitants past and present Now Prof. Pearson has given the first adequate account of the skull of their great king To those who have studied Prof Pearson's monograph it must seem particularly ungracious on the part of a Scotsman to allow such carping criticism as he has just made above to escape from his pen, for in his final paragraph Prof. Pearson makes an appeal which must dissipate the "Scots-wha-hae-ism" of the most stony-hearted native of North Britain. There the great biometrician writes thus "Even the aged dream dreams, and I should like to see a national monument to Bruce at Westminster, an effigy based on the skull as only a great sculptor could conceive it But it should be the gift of Englishmen only to the united nations. . . . The union of our nations needs no artificial cement, but it would be a graceful act for Englishmen to present Scotsmen with what at present they lack, a real characterisation—which I hold is still feasible—of one of their great heroes"

Far be it from the writer to damp in the slightest degree so gracious a proposal, and yet there may be some who will think that Prof. Pearson, while he gives with one hand, does take somewhat away with the other. He suspects that Robert Bruce may have been the subject of syphilis—a suspicion which never crossed the minds of the very able medical men who examined the king's skull and bones when they were disinterred. The writer has searched the pre-medieval graves of England and Scotland for traces of syphilis and found none, and those who know our medical records believe that Robert Bruce had been asleep in Dunfermline Abbey for two centuries before this fell disease appeared in Britain.

A. KEITH.

Biographical Byways.[1]

By Sir ARTHUR SCHUSTER, F.R.S.

9. GEORGE GABRIEL STOKES (1819–1903).

THE collection of Sir George Stokes's published papers, together with the "Memoirs" and scientific correspondence edited by Sir Joseph Larmor, contain such an excellent account of Stokes's activities and personality that nothing remains but to confirm, illustrate, or emphasise what is already on record

Stokes was elected as one of the secretaries of the Royal Society six years after the constitution of the Society had been altered by the limitation of the number of fellows elected annually. It was a critical time, and though there was no sudden change in the policy of the Society, new traditions had to be established The range of his knowledge, the width of his sympathies, and his almost infallible judgment peculiarly fitted Stokes for a position which offered so many opportunities of advising striving and sometimes stumbling men, and guiding their work into profitable directions

My own experience was similar to that of many others. In the account I gave of Osborne Reynolds, I mentioned a certain experiment which I had performed demonstrating that the motion of the radiometer was due to internal stresses. The paper describing the experiment was sent to the Royal Society and I received, in due course, a communication from Stokes forwarding some suggestions made by the referee I complied to the best of my ability, and in informing me that the paper had been ordered to be printed, Stokes added, that in his judgment the paper was not improved by the changes I had made in deference to the referee. He further made a significant remark, which is worth remembering by those charged with the difficult and responsible task of reporting on papers. It was to the effect that, in his opinion, it was best to allow the authors of papers to express what they had to say in their own words, even when improvements might be effected When I quoted this remark to Maxwell a year or two later he told me that he had been the referee, but I believe he agreed with the general principle. The suggestions which Stokes himself so frequently made to the authors dealt with matters of principle rather than with the manner of expression.

I have in my possession five letters written by Stokes during March and April 1885, and dealing with a subject on which there has been, and still is, a good deal of misapprehension The question at issue is referred to in the correspondence of July and August 1899, reprinted in the "Memoirs," vol. ii. pp. 123-125.

Stokes writes to Rayleigh in July 1899:

> "Some years ago Thomson or Kelvin (I forget which he was then), you, and I were together at the Royal Society, and Kelvin asked me what I thought of a result you had arrived at that the appearance of bands of interference in a spectrum did not prove regularity in the light, but only high definition in the spectroscope. If this meant what it appeared to mean I utterly disbelieved it, it seemed so manifestly untrue."

In his reply Rayleigh writes:

> "I am afraid that I shall stand condemned, for I do think that 'a vast succession of independent impulses following one another casually' would show interference, of course with the aid of a spectroscope."

My correspondence with Stokes, which took place fourteen years earlier, deals with a design for an experimental arrangement suggested by him, which it was hoped would give "a large retardation of one of two interfering streams of light relatively to the other, and yet having the bands in one part of the spectrum so broad as to be easily observed, unless that should be prevented by the irregularity of the vibrations of the incident light."

The method depended on introducing into one of the interfering streams of light a dispersive medium, having a length adjusted so as to make the difference in path measured in wave-lengths in the two streams equal to each other within a certain range of the spectrum, in a manner suggested by that adopted in achromatising lenses I do not now remember what ultimately prevented the investigation from being carried out. When I examined the question some years later (*Phil. Mag.*, June 1894) in the light of Gouy's and Rayleigh's discussion of the subject, I was fully converted to their opinion, but I do not believe that Stokes was ever convinced In my judgment, the effect anticipated by Stokes in his arrangement would have been observed with sufficiently great resolving power, but it would have taught us nothing on the regularity of the incident light, because the observed regularity would have been introduced by the resolving power

During my stay at Cambridge, many tales were current with regard to Stokes's taciturnity My own experience is in the other direction. On several occasions I sat next to him at College dinners, but never had any difficulty in finding a subject of conversation on which he would enter with pleasure and sometimes with animation He had several interesting tales of his intercourse with Brewster, who never could be made to abandon the corpuscular theory of light. Even when Foucault had proved that light was transmitted more slowly through water than through air, Brewster refused to give in.

Stokes was an old man when he died, but his scientific outlook always remained young. New ideas pleased him, and he delighted in hearing of experiments that did not fit in with any of the accepted theories His peculiar form of wit is referred to in the "Memoirs," and I recollect one instance of it. At an excursion, during the celebration of the Kelvin Jubilee at Glasgow, Rontgen's discovery of the X-rays was referred to in the presence of some of the foreign delegates Quincke stood up for the claims of Lenard, whose work according to him had to some extent anticipated Rontgen. Stokes replied: "Lenard may have had the rays in his brain but Röntgen got them into other people's bones." Whenever I afterwards met Quincke he never failed to repeat this remark with enjoyment.

The strong religious opinions held by Stokes are well known. I am told, on trustworthy authority, that he voted against the extension of university privileges to

[1] Continued from p. 271.

non-conformists, but this should not be taken as an indication of any want of religious tolerance. His whole life would contradict such interpretation. He could only have acted under a strong sense of personal responsibility.

In the sketch of her father's life, Mrs. Humphrey writes (vol. i. p. 6): "As a little boy he was subject to violent though transient fits of rage . . ." I was interested in this remark, but not altogether surprised, because I once saw an almost ferocious look on Stokes's face. It was at a meeting of the British Association when he thought that some one was taking a liberty with him. But this look was quickly replaced by his usual smile, as he turned round and saw that it was only Lord Kelvin patting him on the back.

Stokes lived a long and useful life, alert and vigorous almost to the end. There are few men who have secured the esteem and love of their fellow workers to the same extent. I shall always remember Lord Kelvin, as he stood at the open grave, almost overcome by his emotion, saying in a low voice: "Stokes is gone and I shall never return to Cambridge again."

The Vision of Nocturnal Animals.

By Prof. S. Russ.

IN some experiments, conducted with Dr. J. C. Mottram during the War, upon the best conditions for night vision, the question arose as to what part the transparency of the media of the eye plays in determining acuity of vision in dim lights. It is known that individuals vary between wide limits in their night vision, some appearing almost blind in a night of average darkness Further, it is known that many wild animals have very little difficulty in making their way about or in finding their prey in dim lights, though the sense of smell may not, in the latter category, be neglected. In the night owls this sense is, I understand, excluded, for they find their prey solely by the sense of sight.

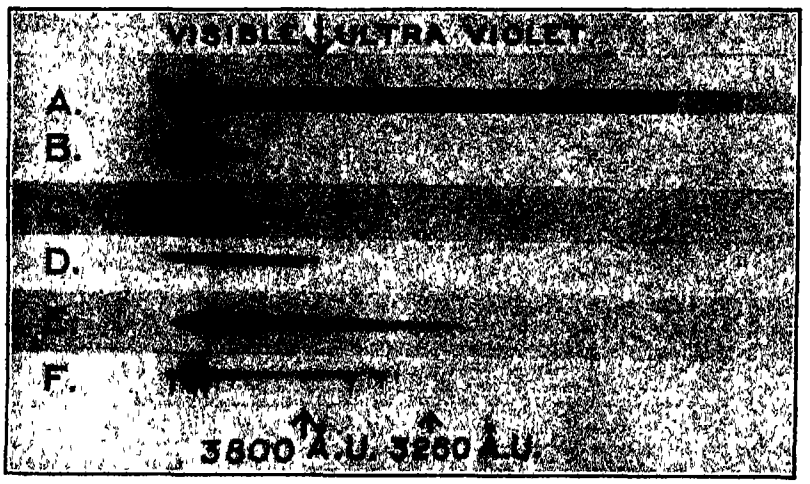

FIG. 1

Experiments of a direct character were made upon the enucleated eye by cutting away a small portion of the retina at the back of the eye and cementing over this aperture a thin quartz plate. It was generally possible to do this without loss of fluid or deformation of the eye; this was now mounted in front of the slit of a quartz spectrometer, and the extent to which the radiation from an arc (cadmium or tungsten) was transmitted through the eye was measured photographically. It was soon evident that all of the eyes tested exerted, as was expected, a considerable degree of absorption for the major portion of ultra-violet radiation from the arc, but that what appear to be significant differences were shown by the eyes of different animals.

In Fig. 1 are collected the results of a number of such experiments: The strip A is a photograph of the ordinary arc spectrum of cadmium; the remaining photographs are with the experimentally mounted eyes interposed between the arc and the slit of the spectrometer. B shows the transmission by a human eye; and the other strips transmission by eyes of a lioness, C; a bear, D, great eagle owl, E; and a tiger, F. Others tested were the eye of an ox, which showed about the same degree of absorption as the human eye, and a cat, which closely resembled that of the tiger. Three human eyes were tested, and they showed no important differences from one another. How far the different degrees of transparency shown are dependent upon post-mortem changes, it is scarcely possible to say; it may be mentioned, however, that the human specimens were probably fresher than any of the others, yet they showed the greatest opacity to the short wave-lengths.

On testing in the same way the various parts of the eye, it was found that the lens was a more absorptive element than the cornea, the humors of the eye being more transparent. It is interesting to note that, if a person is examined in pure ultra-violet radiation, the lens is seen to fluoresce vividly, the cornea less so. The sensation when one is subject to this invisible radiation is that of the eye being filled with a pale blue light.

At a meeting of the Ophthalmological Section of the Royal Society of Medicine on January 9, these observations were discussed in their relation to night vision. If it be a fact that the eye of the nocturnal animal or bird is transparent to a certain range of ultra-violet radiation, and that this reaches the retina in an appreciable quantity, it may be that it is a valuable aid to vision. In the discussion, Sir John Parsons questioned the value of such a radiation to an eye chromatically adjusted to the visible region, but little is known about the range of radiation for which the optical parts of these eyes are most efficiently adapted. Prof. Hobday mentioned that, during the War, Australian horses were used in Palestine for night work, because they did not suffer from night-blindness.

Obituary.

DR. HORACE T. BROWN, F.R.S.

A PENALTY of living is to outlast one's friends, especially the oldest, earliest and most esteemed. Not long ago, I engaged in the impossible task of painting a picture of James Dewar, whom I first met in 1875. Now, the call comes for a portrait of Horace Brown, my fellow-student in 1865, the last of the great Burtonian chemical quartette—Peter Griess, Cornelius O'Sullivan and the brothers Brown. My palette must be cleaned and charged anew with very different colours—the lights and shades to be depicted are of another order. No two persons stand in greater contrast. The one a man of fire and fury, a volcano of surging impetuosity, astounding in his individuality—the other, one of Nature's gentlest men, though adamant in purpose, gifted with a placid personality and a refined urbanity and charm of manner which won for him a large circle of devoted friends, scarce a detractor. Both were philosophers but the one was a consummate artist and actor, the other a naturalist from birth and, though not born to blush unseen, sparing in criticism, reticent and retiring, a conformist in most matters.

Horace Brown was congenitally fitted to walk the paths of chemistry on vital territory. Few are, strange to say: the mentality of most chemists being definitely mechanical and physical; only the elect seem to be able to sit quietly on "the dear old Nurse's knee." He was pre-eminently happy when wandering in her company, whether in the open field or in the laboratory—unveiling the activities of micro-organisms and separating the sheep from the goats, wet-nursing the barley-embryo or tracking the nimble molecules of carbon dioxide, through the stomatal openings, on their way to destruction and burial as sugar and starch in the vegetable cell. The secret of his success lay, I think, in his great powers of application and concentration and the faculty he had of getting up the subject he wished to explore, by prolonged preparatory study.

I have told the story of the family in my notice of Adrian Brown, his half-brother. He was a posthumous child, born July 20, 1848. His father began life as a farmer, so he came from the soil, as he once said to me. His mother's remarriage, to Edwin Brown, brought him under the care of a man of high attainments and wide culture, an ardent naturalist—so he grew up under most favourable conditions. His scientific leanings were such that he began to study the stars seriously in his out-of-school hours when only twelve years old. A year or so later, electricity caught his fancy. Following a book which he found in his stepfather's library, he made a frictional machine and a Leyden jar, which gave him great joy; he even went so far, that he constructed a galvanic battery, with which he studied electrotyping. The fortunate gift of a microscope, when he was twelve or thirteen, made him an ardent and systematic microscopist—thus qualifying him to use the instrument with facility and success in his later technical career. When about fourteen, the discovery of a retort and pneumatic trough among his stepfather's possessions led to his preparing oxygen. This he regarded as the turning point in his career. He then came to the conclusion that he must be a chemist: in early life he had aspired to be a railway signalman. Beginning his experimental work in the kitchen, he soon came to regard a whiff of sulphuretted hydrogen as more precious than the odour of violets—but not so the cook: so he migrated to a store-room. He left school at sixteen and a half By then, in his attic workshop, quite unaided, he had mastered simple qualitative analysis, with the help of Fresenius. He also did a little quantitative work, under guidance of the great Peter Griess, in the laboratory at Allsopp's brewery.

Contrast Brown's training with that of the public schoolboy of to-day—who is not allowed to do anything of his own accord but constantly drilled into dull habits of conformity and helpless thoughtlessness: moreover, there are no waste places in the Flat-land of to-day. Where then is the "Dear Old Thing" to find followers in our times? Even country schoolboys are forced to play games and be examined by literary Dryasdusts, instead of willingly wooing and examining her. Little wonder that we complain that we no longer have leaders. The made-blind will never lead.

Horace Brown left school at the end of 1864, in the Sixth. In April 1865 he passed from Burton-on-Trent to the Royal College of Chemistry, Oxford St., London, to become a student first under Hofmann, then under Frankland. He left at the close of the year, however, to enter the brewery of Worthington and Co. at Burton, as an apprentice, the youngest of three assistant brewers. He was to receive 50*l.* the first year and only 90*l.* in the fifth. The young chemist to-day grumbles at 250*l.*-300*l.* There was no brewing chemistry in those days, even a prejudice against it; the brewer, in fact, was an empiric. Brown could only work in his scanty leisure hours, *sub rosa*, *privatim*, in a garden laboratory, which his stepfather had built for him, in 1866. He here began some research work, at Griess's suggestion. It took him nearly two years to persuade the authorities to purchase a balance and apparatus with which he might determine the original gravities of beers but this was installed in the office. Then came an opportunity which he at once took. In those days, liquor (water) was the dominant spirit in beer—everything that happened—every bad thing—was set down to water. So when Frankland and I, early in 1868, made known our method of determining organic matter in water, he readily obtained leave to spend the slack summer period in London, in Frankland's private laboratory. Having learnt to use the special appliances our method involved; among others, the Sprengel pump—which we were the first, after Graham, to adapt to practical purposes—and its tricks, he returned to the brewery and was allowed to fit up a laboratory. What that laboratory has been worth indirectly to the industry, it would be difficult to say—certainly a good round number of millions.

Brown forthwith made a survey of the Burton water supply, including the river. He thus became an authority on the subject and was instrumental in securing the abolition of the parish pumps, veritable cesspools—although only of age. As the ills that beer was heir to could not be traced to the water, he now devoted himself to the microscopic study of yeasts and soon became aware of their "mixed" character. At this period,

though not until 1870, Pasteur's great work, perhaps his greatest, "Études sur le vin" (1866), came into his possession and the already loosened scales soon fell from his eyes. It became clear that the souring of stock ales was comparable with the souring of wines. When Pasteur's "Études sur la bière" was published in 1876, he had little to learn from its microscopy. Meanwhile, he had perfected a method of "forcing" beers. This involved the use of a rectangular copper box or tray containing water, kept at a regulated temperature, considerably above the average atmospheric (80°-85° F.). Samples of the beers, in small closed flasks, provided with a side tube dipping into a mercury seal, were kept on the tray during several days; the deposit was then examined with the microscope and the extent determined to which pirate organisms had developed. It was then easy to forecast the behaviour of the beers in store and so determine the order in which they should be put on the market. The monetary value of the method to the industry was very great.

Largely owing to Horace Brown's work and influence, brewers quickly learnt to appreciate the value of Pasteur's teachings and soon began to put their houses in order. The progress of bacteriology in Great Britain, especially its application to water supply, was also hastened. Horace Brown, in fact, played the same part in brewing, in leading brewers to clean up their plant and adopt aseptic methods, that Lister played in surgery—he was even in advance of Lister in appreciation of Pasteur, though a much younger man. He became manager of the whole of the manufacturing department of Worthington's in 1873, at the age of twenty-five, and occupied this responsible post until 1889, when he became one of two managing directors on the incorporation of the firm as a limited liability company. He resigned in 1893 and left Burton for London, after which time his work was done privately.

What more Horace Brown accomplished before and after he left the brewery cannot usefully be told here. Suffice it to say that he was recipient in succession of the Chemical Society's Longstaff Medal, of a Royal Medal and eventually of the Copley Medal of the Royal Society—only given in recognition of outstanding service to science. His work is noteworthy on account of its thoroughness, the elegance of his methods and the philosophical manner in which he discussed the fundamental problems which engaged his attention. He was one of the few chemists who have done pioneering work of real importance in the biological field, notably in botany.

In the interval since Brown and I became friends, science is certainly risen: its power is certainly proven. Still, it is in some measure fallen—the public effect is not that anticipated by Huxley, Tyndall and others. The clerics openly scoff at our failure and do not sense our one supreme object—the discovery of truth, how infinitely superior belief through such discovery must be to all belief through mere faith, how perfect a religion must eventually be framed through it.

The lesson of Horace Brown's education and life is to be pondered by those who realise how complete a failure is the teaching of "science" in our schools and even in our universities, as a means of inculcating in the community an appreciation of its method and majesty and its usefulness. HENRY E. ARMSTRONG.

DR. E. KLEIN, F.R.S.

WITH the death of Dr. E. Klein at Hove on February 9, one passed away who had played an important part in English medical science for more than half a century. It is not an easy thing to give a complete account of him or to estimate accurately the value of his work. He had been with us so long that but few of his early contemporaries survive, while the younger workers from whose lives the War subtracted years knew him merely as a name, and had probably never seen him. Indeed, he was a somewhat elusive personality to all of us, as he kept a good deal to himself. The present writer knew him as a fellow-worker in the same branch of study, and had also dealings with him of a scientific kind. Much of what has been written of him since his death will be found to be incomplete and inaccurate. Our claims to write of him rest on information derived from two friends who knew him intimately half a century ago, on a personal acquaintance with him for half this time, and on an intimate study of almost all his works, a study with which we have refreshed our memory since his death.

Emanuel Klein (the name Edward was assumed only after his arrival in England) was born in 1844 at Osijek (Essek), the chief town of Slavonia, situated near the junction of the Drave and Danube. His father was a tanner of Russian leather. Nothing is known of his early years, but he related himself that he was in London when about eighteen—possibly in the capacity of a tutor. His medical education was in Vienna, and after graduation he carried out original investigations, chiefly embryological, in the laboratory of Salomon Stricker (1834–98), at that time professor of general and experimental pathology in the University. In 1871–73 Stricker was publishing his great "Handbuch der Lehre von den Geweben des Menschen und der Tiere," and for this work Klein wrote the articles on the thymus gland, the external generative organs, the serous membranes, and, in collaboration with Verson, the article on the histology of the intestinal canal, and, with Stricker and Stieda, on the conjunctiva and sclerotic. Klein's original work was, however, mainly embryological in connexion with the development of the vascular system of the chick. Stricker's Handbuch was translated into English by Henry Power for the New Sydenham Society, and Klein came into contact with several English workers.

When the Brown Institution was started in 1871–2 by the purchase of two houses in Wandsworth Road, Burdon-Sanderson applied to Stricker for a suitable resident assistant director, and Klein being recommended, he came to England and lived in one of the houses (now turned into shops). He was well received, and proved a *persona grata* from the start. In those days a number of the more ardent young consultants, such as J. F. Payne, Cavafy, and Pye-Smith, used to forgather at his house to discuss science, and incidentally to play whist. Klein had also some private pupils, among whom were Francis Darwin, Frederick Treves, Jeremiah MacCarthy, and James Adams. In 1873 he was appointed to give a course of lectures on histology in Morrant Baker's physiological course at St. Bartholomew's Hospital, and thus began his long association with this ancient and noble institution, first

as teacher of histology and later of advanced bacteriology. Here also was done most of his work for the Medical Department of the Local Government Board after he left the Brown Institution.

Almost all Klein's early work was on histology, a branch in which he was and is an acknowledged authority. In 1873 he wrote the section on histology for the "Handbook for the Physiological Laboratory," edited by Burdon-Sanderson, Foster, Brunton, and Klein. In the same year he published an authoritative work, in two parts, entitled "Anatomy of the Lymphatic System." These volumes were profusely illustrated with beautiful drawings by Klein from his own preparations, and he exploited with great success the method of silver impregnation which was introduced into histological technique by von Recklinghausen (1860). In 1875 Klein was elected a fellow of the Royal Society His reputation as a histologist was greatly increased by the publication, in conjunction with the orthopædic surgeon Eldred Noble Smith (1847–1906), of the classical "Atlas of Histology" (1880). The forty-eight magnificent plates in this work were drawn by Noble Smith from Klein's preparations, and some of the illustrations have been copied into almost every English book on anatomy and physiology down to the present time. Klein also published a standard "Elements of Histology," which ran through many editions and was translated into several foreign languages.

We have dealt in some detail on Klein's activities in histology because we feel convinced that, although this occupied chiefly his earlier years, it is the work by which he will be best and longest remembered. He was brought to England not as a normal histologist, but to engage in the histological problems connected with disease, and he drifted into experimental pathology and bacteriology, as we think, *malgré lui*. He lived and worked untiringly throughout the whole of the classical period of bacteriological science from 1876 to 1900, and it is greatly to be regretted that his name cannot be placed alongside those of Pasteur, Lister, Koch, Loeffler, Roux, Pfeiffer, Weichselbaum, Kitasato, Behring, and Ehrlich, as the discoverer of any really important ætiological agent of disease. Indeed, it may sound like a paradox, but on more than one occasion he failed at first to confirm work which has become part of established bacteriological knowledge. This is difficult to understand, for, at any rate in his later years, he was a splendid technician, and frequently exhibited beautiful cultures of bacteria. We are inclined to think that his failure to make any bacteriological discovery of the first rank was due to the fact that he arrived on the field just a few years too soon. When he began the investigation of disease the methods in vogue were microscopic only. Cultivation was practically unknown or carried out by methods now admitted to be insufficient. Bacteriology really emerged through the genius of Koch, and at a time when Klein was labouring with the old methods. Had he been in a position to become associated with a master of technique like Koch, he must with all his skill have succeeded in grasping at least one of the golden prizes which were falling into the hands of the workers in Germany and France.

There is a good deal of evidence in Klein's writings that his control experiments were too scanty or incomplete, and this led him to hasty conclusions on more than one occasion. Although it is to be regretted that Klein had not the luck to make a really important discovery in bacteriology, he exercised a profound and beneficial influence in England on the applications of the science to public health problems, and may be said to have controlled this branch for nearly half a century in a manner which was greatly to his credit. In personal intercourse with the younger workers he was always most helpful and generous, and placed his great experience at their service. All the memories of him in the country of his adoption will remain favourable. He was a tall, handsome man who spoke broken English to the end. Of affable manners, he was often polemical, but took defeat in a thoroughly sportsmanlike fashion. Throughout life he showed the characteristics of his race in a passion for music and chess.

W. B

HUGO VON SEELIGER, who died on December 2, was born at Bielitz-Biala, Austria, on September 23, 1849. After studying at the universities of Heidelberg and Leipzig, he was appointed observer at Bonn Observatory in 1873 and remained there for four years, taking part in the observations of the zone 40°-50° for the Astronomische Gesellschaft Catalogue, and being a member of the expedition to observe the 1874 transit of Venus. After a short period at Gotha he went to Munich in 1882 as Director of the Observatory and professor of astronomy He remained there for the rest of his life, and became famous as a teacher, Schwarzschild having been one of his pupils. He also made several theoretical researches both on stellar problems and those relating to the solar system. He was a pioneer in the application of statistical methods to the study of star density, and the size and shape of the stellar system, his estimate of the absorption of light in space was 0·3 mag. in 12,000 light years. He was interested in the excess of the motion of Mercury's perihelion over its theoretical value He examined whether any distribution of the matter forming the zodiacal light could explain this, without introducing other anomalies in the motion of the nearer planets. Another study related to the brightness of Saturn's ring. Basing his work on Maxwell's deduction that the ring was composed of small particles, he obtained expressions for its change in brightness at different distances from opposition, which were verified by Muller's photometric observations.

WE regret to announce the following deaths.

The Right Hon. Sir Thomas Clifford Allbutt, K.C.B., F.R.S., Regius professor of physic in the University of Cambridge since 1892, on February 22, aged eighty-eight.

Mr. T. H. W. Idris, president in 1903 and 1904 of the British Pharmaceutical Conference, on February 10, aged eighty-two.

Sir T. Edward Thorpe, F.R.S., emeritus professor of chemistry in the Imperial College of Science and Technology, South Kensington, and president in 1921 of the British Association, on February 23, aged seventy-nine.

Current Topics and Events.

THE President and Council of the Royal Society decided at a meeting on February 19 to recommend for election into the Society the following fifteen candidates Dr. W R G. Atkins, Prof C. A Lovatt Evans, Mr R H. Fowler, Dr F. A Freeth, Dr Walcot Gibson, Dr Harold Jeffreys, Prof. F Wood Jones, Prof J. Kenner, Prof. E Mellanby, Mr J A Murray, Prof. J Proudman, Mr R V. Southwell, Dr L. J. Spencer, Dr R. J. Tillyard, Prof. R Whiddington.

THERE has been so much adverse criticism of the Wireless Telegraphy and Signalling Bill recently introduced by the Postmaster-General that we are beginning to wonder whether after all something cannot be said in favour of it. Every one must admit that some control of "etheric" waves is absolutely necessary, even if the terms in which the Postmaster-General asks for authority are open to question. Scientific men, although they know perfectly well what the framers of the Bill mean by "etheric waves," have taken a Puckish pleasure in destructive criticism of the nomenclature. When asked to give a scientific definition they have to confess their inability A proposal has recently been made for a large and powerful radio station which will control the time-keeping of clocks Railway engineers want to use radio signalling to control their trains It is obvious that if some one were not put in authority, the ether—if there is an ether—would soon be in a chaotic condition. If anything affects telegraphy or telephony, the Postmaster-General has been given in the past, and still possesses, the most absolute powers to prevent this interference taking place. During the War, the public welcomed the autocratic powers given to the Post Office If there were another war these powers would be at once resuscitated for the public benefit The Bill has been in preparation for two or three years, and most of those affected by it have been consulted If suitable amendments be introduced so that the regulations do not affect amateur research injuriously, and section 7, which perhaps goes too far in putting the methods of radio power transmission under the control of the Post Office be suitably amended, we see little to criticise in the Bill. Regulations are always grievous at the start, but they may nevertheless be for the public good.

IT is of interest, just now, to recall the connexion of the Royal Society with various experiments made in 1664 from the steeple of old St. Paul's, under the guidance of Robert Hooke. Oldenburg, the Society's secretary, writing to Boyle, on August 25, 1664, reports that having found the top of Paul's steeple a convenient place for experiments, order was given at the previous day's meeting of the Royal Society (held at Gresham College) to try there the descent of falling bodies, the Torricellian experiment, and the vibrations of a pendulum suspended so as to reach to the floor of the church, a perpendicular height of about 200 ft. Hooke began at once to make trials, enlisting, as helpers, "some other company," which, we gather, included Lord Brouncker, Dr. Wilkins, Sir Robert Moray and Dr. Goddard Hooke comments on sundry difficulties in a letter to Boyle, dated Sept. 8, 1664. He says: "the steeple being without any kind of lofts, but having here and there some rotten pieces of timber lying across it, I caused a rope to be stretched quite cross the top, and fastened; in the midst of which I fixed a pulley, through which I let down the string and weight to the bottom, for only in the very middle of the steeple was there a broad clear passage from top to bottom." The vicissitudes of issue of the "Philosophical Transactions" have curious connexion, too, with old St. Paul's and the Great Fire of London in 1666. The Royal Society's printers (Mr Martyn and Mr. Allestry) and the booksellers in St Paul's Churchyard lost their stock of books in the conflagration, after carrying them from their own houses into St. Faith's Church, under St Paul's Among the losses were all the copies then printed and unsold of the "Philosophical Transactions." It is small wonder that early copies of this scientific journal are rare

WE have recently had occasion to consider in these columns the recommendations of the Departmental Committee on the Use of Preservatives and Colouring Matters in Food. The Minister of Health has now published draft regulations based on these recommendations, and in framing them he has apparently adhered closely to the latter. The preservatives formaldehyde and boric and salicylic acids are completely prohibited: benzoic acid and sulphur dioxide are allowed in certain cases only and in strictly limited amounts The following may contain sulphur dioxide: sausages, jam, fruits, beer, cider, wine and cordials and fruit juices: benzoic acid is only permitted in coffee extract, fruit juices and cordials and sweetened mineral waters, including brewed ginger beer; but no article is permitted to contain both sulphur dioxide and benzoic acid. As regards colouring matters, all colours which are compounds of the following metals are prohibited: antimony, arsenic, cadmium, chromium, copper, lead, mercury, zinc. In addition, gamboge and half-a-dozen coal-tar dyes, including picric acid, are also forbidden. Further to protect the consumer, it is laid down that sausages, jam, and coffee extract must be labelled if they contain preservative, whilst articles sold as preservatives must be labelled with the percentage of sulphur dioxide or benzoic acid present. The regulations will apply to imported as well as to home products. Full powers are taken to carry out inspections and take samples. The regulations, when put in force—no date is as yet mentioned—should do much to improve the quality of Great Britain's foodstuffs.

THE American Association for the Advancement of Science has about 13,000 members, and in his address as retiring president (*Science*, January 2), Dr. Charles D. Walcott considers how this great body can render science of service to mankind. It should, he says, "act as a liaison agency between professional science and the public, as well as between the various sciences." Whether it be in the traffic and social problems of modern life, or in the conservation of

natural resources, the great need is the education of all citizens in the scientific method of approach. "All scientific men and women may do their bit—first, by training themselves to observe accurately, to think straight, and then to record clearly and honestly, and to draw warranted conclusions based on the facts presented . . ., second, by reviewing the mass of technical information with which they are familiar and telling the story they have learned in simple, clear language, free from obscure, complicated, technical and verbose wording" They should engage in co-operative public work, applying the scientific spirit in all branches of social endeavour, and notably in all agencies concerned with the education of the people from the university to the cinema. Could not, Dr. Walcott concludes, the Association organise a committee to deal with the popularising of scientific knowledge, bringing its lessons and its principles home to all—and particularly to children, to women, and to business men? This is admirable counsel, and just as applicable to those on the eastern side of the Atlantic as to Dr Walcott's fellow-citizens.

AT the sale of the Crisp Collection of antique microscopes on February 17, high prices were realised for some of the instruments. The silver "universal" by G. Adams was obtained by Mr. Webster for 360*l*. This instrument, on account of its highly ornamental construction, its scientific interest, and the fact that it is made throughout of silver, was easily the most valuable item from the auction point of view. The original modification of the Hooke microscope, dating from about the year 1675, realised 160*l*. The name of the maker of this very fine early example of English opticians' work is unknown An original compound microscope made by Guiseppe Campani, the great Italian optical instrument maker, was obtained by the Science Museum, South Kensington, for 45*l*. Other instruments of historical and scientific value secured for this museum included the improved "universal" microscope by G. Adams, the Cuno form of hand microscope made by Depovilly of Paris, and a modified form of John Marshall's microscope. For the new Museum at Oxford, several instruments were obtained, including a replica of Hooke's original compound microscope, as figured and described in his "Micrographia," 1665. This item realised 20*l*. Mr. T. H. Court, whose valuable collection in the Science Museum is well known, secured a large number of the instruments. Of these, the elaborately decorated microscope made for Pope Benedict XIV. (31*l*.), the very fine microscope made in 1752 by D. Joannes de Guevave (33*l*.), and an early Italian microscope inscribed "Elaboratum a Blasis Burlini Venetiis Optico" (31*l*.), may be mentioned. Three fine examples of the Marshall microscope, made in the early part of the eighteenth century, were sold at prices ranging from 13*l*. to 22*l*.

PROF. T. H. PEAR, in a discourse at the Royal Institution on Friday, February 20, on "Acquiring Muscular Skill," stated that his purpose was, first, to examine an urgent practical aspect of the problem; the desirability of describing and recording skill in a universally acceptable language and notation. The photographic, stereoscopic, cinematographic, and ultra-rapid cinematographic study of the ideal postures and movements desirable in certain skills, and the result of describing and discussing such records in words, have occasionally led to a degree of "intellectualisation" which is not generally recognised. The accidental fact that some skills have been more fortunate in their exponents partly, but only partly, accounts for this. By the aid of these various devices and of certain utilisations of "picture-diagrams" and films it is possible not only to record actual performances, but also to criticise them analytically. The study of modern figure-skating in the international style is a good illustration of this point. Suitably prepared diagrams should help the learner, before he attempts to execute a complicated series of movements, to grasp them visually, both in parts and as a whole This method of transmitting skill is probably in its infancy. Its progress in the hands of suitable instructors should be rapid. Whether such visual means of approach to the mind are specially suitable only to the person who "thinks in pictures" is an important and unsettled problem By these means it should be possible to compose new skilled movements and new combinations of them Before the days of musical notation and of writing, musical composers and poets had to be performers. Nowadays they may inspire other more gifted executants. This may be possible for skilled movements when a combination of workers, players, anatomists, physiologists and psychologists produce a grammar, a syntax, a harmony and a recorded poetry of movement

IN his presidential address to the Optical Society on Thursday, February 12, Prof. Archibald Barr referred to the optical instrument maker as the tool-maker for all branches of scientific investigation including his own. He stated that scientific investigators depend to a great extent on the knowledge and skill of the optician for the provision of their tools. Every improvement made in the optician's products enables the user of these tools to go farther and deeper in his researches. It is the duty of the optician to keep himself familiar with the latest advances in science, so as to be ready to forestall the needs of the investigator, or to be able fully to understand the requirements that arise, and to bring to bear on the production of the new tools an intimate knowledge of the means by which, and the extent to which, the requirements can be fulfilled in a practicable device. Opticians are primarily concerned with less than one octave out of the sixty or more of known radiation, though for some purposes they have to take account of one or two octaves on each side of that of visibility, into the infra-red and the ultra-violet. Narrow as it may be on the scale of radiology, the one octave of the visible spectrum has and always will have a very special significance in the scheme of things as they are, and that octave includes a wide range of problems of all degrees of complexity. Within the limits of optics properly so called, there is still scope for development to which no limits can be set.

PROF. WILLY WIEN, of Würzburg, has been elected an honorary fellow of the Physical Society of London.

MR. E. HILTON YOUNG, M.P., has been appointed chairman of the Departmental Committee on the University of London, in succession to Lord Ernle, who has resigned.

DR LOUIS A. BAUER, director of the department of terrestrial magnetism of the Carnegie Institution of Washington, has been elected a corresponding member of the Russian Academy of Sciences.

WE learn from *Science* that Mr John F. Stevens, of New York City, has been awarded the John Fritz Gold Medal of the Engineering Foundation, New York, "for great achievements as a civil engineer, particularly in planning and organising for the construction of the Panama Canal, as a builder of railroads and as administrator of the Chinese Eastern Railway."

A TEMPORARY assistant and a temporary junior assistant are required in the metallurgical research department of the Royal Arsenal, Woolwich Candidates should be graduates with university training in metallurgy Applications for the posts should be sent, with copies of not more than three testimonials, to the Chief Superintendent, Research Department, Royal Arsenal, Woolwich, S E 18

A TECHNICAL assistant is required at the Royal Aircraft Establishment, South Farnborough, Hants, for experimental and development work in connexion with aerial beacons and aerodrome illumination generally. Candidates should possess an honours degree in electrical engineering, design experience in the application of optical and illuminating engineering, and, if possible, experience in lighthouse work Applications, marked A 47, should be sent to the superintendent of the establishment

APPLICATIONS are invited for the position of organising secretary to the standing committee on special libraries and bureaux of information His duties will consist of attending meetings of the standing committee and its executive, the compilation of a directory of special libraries and intelligence bureaux in the United Kingdom, and preparation for the second conference to be held in September 1925. Applications giving full particulars, and endorsed "Special Libraries," should be sent to reach Mr J. G Pearce, Central House, 75 New Street, Birmingham, not later than March 10.

THE annual general meeting of the Institute of Metals will be held at the Institution of Mechanical Engineers, Storey's Gate, Westminster, S.W.1, on Wednesday and Thursday, March 11 and 12, commencing each day at 10 A.M Twelve communications are due for presentation at the meeting. The annual dinner will be held at the Trocadero Restaurant on Wednesday, March 11, at 7 P.M. Amongst those who have accepted the Council's invitation to be present at the dinner are the Right Hon. Neville Chamberlain (Minister of Health), the Right Hon. the Lord Morris (vice-chairman, Imperial Mineral Resources Bureau), and the presidents of many kindred societies.

DR. H. C. WILLIAMSON has been appointed to investigate the salmon of British Columbia at Prince Rupert Dr. Williamson was a distinguished student and graduate of St. Andrews as well as holder of a research studentship of the Exhibition of 1851. Trained in fisheries work at St. Andrews, then for nearly two years at Naples, and afterwards in Germany, he entered on the scientific work of the Fishery Board for Scotland equipped as few have been with special knowledge and experience. For twenty-eight years he has carried on a continuous series of researches, illustrated by his own skilful pencil, on food-fishes, edible and other crustaceans, and has made careful experiments on the eggs of salmon and herring in connexion with their transmission to the antipodes, besides other fisheries' subjects, and has at present a work on fishes in the press. The loss of a highly trained scientific investigator in Scottish fisheries, following so soon after the retirement of his able senior Dr Fulton, is unfortunate for the Department, yet Canada will be the gainer Dr Williamson's publications in the Reports of the Fishery Board extend from 1893 to the present year

THE council of the Institute of Chemistry announces that the Meldola Medal for 1924, awarded for meritorious work in chemistry during the year, has been awarded to Dr. Leslie J Harris, of the School of Biochemistry and Emmanuel College, Cambridge. Dr. Harris's investigations have been concerned largely with the theoretical basis of acid-base titrations and in special relation to amphoteric electrolytes. His results have been published mainly in a series of papers appearing in the Proceedings of the Royal Society, B, during the past few years He has shown that the protein constituents, amino-acids, may be estimated from a consideration of their individual acid and basic constants, by titrating within definite P_H limits The same principle has been utilised also by Dr Harris for estimating proteins and other ampholytes Recently he has shown that such methods are of general application in chemistry, and serve to estimate substances containing the feeblest basic or acidic groups, it having previously been supposed that acids or bases of less than a certain strength were incapable of estimation by acidimetry. Incidentally he has disproved for many cases the theory of acid-base binding at peptide linkages, and he has brought forward fresh data upon the ionic nature of the protein molecule. Denaturation of proteins he has shown to involve a chemical change which occurs at a hitherto undescribed sulphur grouping in the protein molecule. Dr. Harris has also carried out investigations upon milk and infant nutrition.

IN the notice of the second edition of "An Introduction to the Study of Cytology," by the late Dr. L. Doncaster (NATURE, February 14, p. 224), the reviewer regretted that the scope of the book was not enlarged. We understand from Mr. J. Gray that the omissions mentioned are entirely due to the fact that their inclusion would have involved a considerable increase in the cost of the book. It seemed desirable to keep the book within the means of the average

student, and this would not have been possible in a new edition including even a brief account of recent knowledge of cell inclusions and somatic cells. The new edition has recently been translated into Italian by Prof. L. Cognetti de Martiis, of the University of Turin, and can be purchased for seven shillings

As a result of the amalgamation of the Ipswich Scientific Society and the Ipswich and District Field Club, there has been formed, under the presidency of Mr. J. Reid Moir, the Ipswich and District Natural History Society The honorary secretary is Mr F. W Brinkley, 31 Oxford Road, Ipswich Fortnightly meetings are held, taking the form of lectures in winter and spring and excursions in the summer, and various sections, each under the guidance of a "leader," deal with different aspects of the Society's activities. The Society claims a membership of about 250, and it is hoped to issue shortly the first volume of Proceedings. According to the programme for the 1925 session, Sir Charles Sherrington, president of the Royal Society, who is himself associated with Ipswich, has consented to become patron of the Society, and there is little doubt that the sympathy and encouragement expressed by his interest in the Society will do much to promote appreciation of the value of science in the neighbourhood

In addition to the Monthly Bulletin of the Hawaiian Volcano Observatory, a weekly *Volcano Letter* is now issued Each letter contains the Kilauea report for the previous week on the volcanic phenomena and on the earthquakes recorded at the Observatory, in addition to miscellaneous news On its reorganisation a short time ago, the Volcano Research Association was placed under the U S Weather Bureau. It has now (since last July) been transferred to the U S Geological Survey. Since 1920, it has established earthquake stations at Kone, Hilea, and Hilo, all in Hawaii, in addition to the central observatory at Kilauea, it has conducted boring experiments at Kilauea, equipped a chemical laboratory at the Observatory, and maintained a research fellowship at the station for one year. It is now engaged in preparing for publication the scientific results of its fifteen years' work on the volcano.

We have received No. 2 of *Brighter Biochemistry*, the illustrated journal of the Biochemical Laboratory, Cambridge. As its title implies, it is a product in a lighter vein than is usual in biochemical journals: it contains short articles in prose and rhyme, contributed by various members of the staff of the Laboratory, whose identity is revealed by the initials at the foot of each contribution. As might be expected, a local colour is reflected from most of the articles, and some of the allusions will probably only be fully appreciated by those who have an intimate acquaintance with the members of this school and their works. Perhaps the most amusing contribution is a short one in verse, entitled "The Great Push: another version," giving a brief, though doubtless accurate, account of recent experiments conducted by one of the staff of the Laboratory. A series of cautionary tales for biochemists, and the story of John Montgomery Wardley, are other good things in the number, whilst, as might be expected, blood sugar methods and their authors—we had almost said perpetrators—have not escaped satire at the hands of those who have to use them

The German Scientific and Medical Association (Gesellschaft deutscher Naturforscher und Aerzte) has been greatly encouraged by the success of the Innsbruck meeting in September last. No general meeting will be held in 1925 Severe economy is still necessary. A meeting at Düsseldorf is planned for 1926 *Die Naturwissenschaften* has been made the organ of the Association, and monthly communications are distributed with this journal. The issue of November 21 was devoted to the proceedings of the Innsbruck meeting and included the lectures delivered at the joint meetings of the Society, together with the more important of those delivered to the medical and natural science sections. Men of science of all shades will find something of interest in one or other of these lectures, for the range of subjects covers a wide field A thousand members have accepted the offer of a reduced subscription rate to this journal The membership subscription is 5 marks in Germany, 50,000 kroner in Austria Foreigners may send notes or cheques in registered envelopes to the G D N A at Chemie-Treuhandgesellschaft, Berlin W 10, Sigismundstr 3. For all other business the Secretariat is at Leipzig, Nürnberger Strasse 48[1]. Publications are issued through the Hirschwaldsche Buchhandlung, Berlin, N W., Unter den Linden 68.

We have received Nos. 9-10 of vol. 1 of the *Bulletin d'Histologie Appliquée*, edited by Prof. A Policard, of Lyons. It contains original papers on physiological and pathological histology, a section on methods, a critical review, and a bibliographic index. It is well printed, but the illustrations could be improved considerably. A somewhat original feature is a quotation from some author after each paper: the excerpts cover a variety of subjects, from the use of a theory (Gide) to a diet for white rats (Steenbock). The number contains four original papers. A. Lumière and R. Noël describe the lesions produced in guinea-pigs by the actual method of killing, and conclude that simple bleeding by cutting the carotids, or removal of the heart and lungs after opening the thorax, produce the least alteration in the tissues; all asphyxial methods cause congestion and hæmorrhages. E. Grynfeltt describes the erectile tissue in the fimbriæ of the Fallopian tube, by means of which the abdominal ostium of the latter can be brought close to the ovary. Mlle. A. Van Herwerden gives a short account of a reversible gelation produced in the protoplasm of the living tadpole by means of weak acetic acid. H. E. V Voss describes the ossification and calcification sometimes observed in portions of ovary grafted into the testicle or kidney of a male guinea-pig, and concludes that connective tissue cells are responsible, typical osteoblasts not being observed. In the section on methods, A. Ch. Hollande discusses the oxidase reaction, and finds, as the result of his experiments, that the formation of indophenol blue

in cell-granules is not diagnostic of the presence of an oxidase in them, since the granules take up the blue colour when the dye itself is presented to them. The actual formation of the blue colour, however, shows that oxidases must be present in the cells or their surroundings M. Bernheim reviews the functions of the germ centres of Flemming in the lymph-glands, and concludes that they play an important part in the defence mechanism of the body. The bibliographic index is under headings such as embryology, tissue culture, etc., sections v to ix appearing in this number

THE Medical Supply Association, Ltd., 167-185 Gray's Inn Road, London, has recently placed on the market a compact X-ray outfit of unusual design It is described by them as the "Radiosearch" Complete X-ray Apparatus and is intended for general laboratory work Electricity at 70,000 volts is supplied by a small oil-immersed transformer, enclosed in a rectangular wooden box with ebonite top, which stands in front of a hard-wood panel about three feet high From the upper part of this panel two well-separated stout porcelain insulators project horizontally and forwards To the end of one of these a practical type of milliampere meter with open scale is attached, while the other column carries a variable resistance by which the heating current for the Coolidge tube may be adjusted while the apparatus is in action, a dial enabling the setting to be noted. The high tension leads from the secondary of the transformer are suitably connected to these instruments and pass on over spring pulleys to the X-ray tube itself. The tube is the self-rectifying radiator "Coolidge" with current-carrying capacity of 10 milliamperes at 70,000 volts. It is held axially within a cylindrical box with only the electrode sleeves projecting on either side. The arrangement, adequately protected with lead rubber, is mounted upon a separate and portable table stand so as to enable a beam of X-rays to be projected in any desired direction The outfit is well and strongly constructed Its simplicity and solidity are distinct features, and there seems little to get out of order with reasonable care. It should be noted that no means is provided for the variation of the potential difference at the tube terminals. An attachment can, however, be supplied for this purpose at an additional cost. It would also make the outfit more complete for experimental work if a sphere-gap with resistance were fitted so that the potential difference across the tube could be directly measured. Most physicists using the set, however, would probably prefer to make this measurement by means of an X-ray spectrograph.

Our Astronomical Column.

ENCKE'S COMET.—*Astr Nach* No. 5345 contains some observations by G. A Tikhov of Pulkovo on the spectrum of Encke's comet made on Oct 20, 1914 (46 days before perihelion), and Oct 4, 1924 (27 days before perihelion) An objective prism was employed. The following are the intensities of the principal bands, on a scale from 1 to 10

Wave-length.	Intensity 1914	Intensity 1924	Source
388	10	10	Cyanogen
405	8	4	
473	1	6	Carbon
516	.	1	,,
563	.	1	,,

The 1924 spectrum is of a type often found in comets That of 1914 is unusual in the feebleness of the carbon bands, which is perhaps due to the longer interval before perihelion The continuous spectrum is weak, especially in 1914.

THE NATURE OF SPECTROSCOPIC BINARIES.—According to the theory of binary stars, there is a simple relation between the period and the semi-amplitude, K, of velocity variation This relation involves the masses of the stars; but by assuming an average mass, and treating the stars in groups, it becomes possible to investigate this relation without introducing serious errors This has been done by Dr O. Struve in the *Astrophysical Journal*, vol. 60, p 167, who has found that for spectroscopic binaries with periods greater than 2·5 days, the relation between P and K agrees satisfactorily with theory The Cepheid variables have comparatively small values of K which show no relation to the periods—thus incidentally affording evidence in favour of the pulsation theory, which assumes that Cepheids are not true binaries In addition, the author has discovered an interesting group of stars (to which he has applied the rather unfortunate name of "Pseudo-Cepheids") which closely resemble the Cepheids in the behaviour of K. These are all spectroscopic binaries of short period (less than 2·5 days), and if they are to be regarded as true binaries, the peculiar behaviour of K would seem to imply either that the total masses are very much smaller than the average, or that the mass-ratios are very large—neither of which assumptions is supported by evidence from the long-period binaries.

The evidence brought forward by Dr Struve thus seems to show that short-period spectroscopic binaries may be classed in two groups, some, characterised by large values of K, are true binaries, while others (the more numerous group) are probably not binary stars at all, and bear a close analogy to the Cepheid variables.

THE DIAMETER OF VENUS.—*Astr Nach* No. 5348 contains three articles on this subject by members of the staff of the Berlin-Babelsberg Observatory. It is a matter of considerable interest, owing to Venus being the only known orb that closely resembles the earth in size. The measures are difficult, owing to the extreme brightness of the disc, which produces irradiation, the amount of which is difficult to determine; it has generally been assumed that the amount of irradiation in arc is constant at all distances of the planet, but the researches here described (by G. Struve, J. Dick, and A. Kühl) show that this assumption is untenable. They used the large Babelsberg refractor with various powers up to 1000. G Struve's final diameter is 17·523″ at unit distance; comparing this with the usually adopted value for the earth, 17·61″, we see that the planet's diameter is less than that of the earth by some 40 miles only. That, however, may be modified if the visible disc of Venus is bounded by a cloud surface, as this is likely to be some miles higher than the solid ball of the planet.

ANCIENT ROCK-SCULPTURES IN THE LIBYAN DESERT.—A journey of considerable geographical interest across the southern Libyan Desert from Bara to Bir Natrun in Dongola Province is described by Mr. D. Newbold in *Sudan Notes and Records*, vol. 7. At an early stage of the journey, the author witnessed the departure of the Kababish on their great seasonal migration, when the tribe moves some 20,000 camels and 150,000 sheep and goats to the "gizzu" or grass country for six months. Evidence of early occupation of the country crossed was abundant, including cairns, pottery, some of which was afterwards identified as Meroitic, a small brick pyramid at Abu Sofian, and a find of five glauconite implements of neolithic type. Rock sculptures were first found at Zobat el Hammad, where drawings roughly incised on boulders showed tailed and phallic men, elephants, giraffes, ostriches, oryx, cattle, and several other animals which could not be identified. At Um Tasawin on the return journey, the cliffs, even in the most inaccessible positions, were found to be engraved with innumerable figures of cattle, giraffes, elephants, oryx, and other indeterminate animals. There were also a number of human figures, some tailed, some armed with bows, a few phallic and one steatopygous. At Abu Sofian, two groups of pictures, obviously of the same date and "school," were within a day's march of one another. Here the drawings were incised on round boulders, and were very numerous. Camels are shown literally in hundreds of drawings, giraffes and ostriches still appear, but the cattle dwindle in numbers, while the elephant is not represented and the bowmen give place to men armed with spears and carrying shields. The absence of the camel at Tasawin and el Hammad suggests that the drawings there cannot be later than the first century B.C. They may be the work of the Southern Libyan Tamahu, the ruling caste in Ethiopia in the Meroitic period, and might be dated any time from 300 to 750 B.C. or even earlier. The Abu Sofian groups are obviously later, as shown by the presence of the camel, but must equally be the work of Libyan artists, and are probably between 1500 and 2000 years old. The archaeological evidence as a whole supports the theory of continued migration into the northern Sudan of desert peoples of the west and north-west from the earliest times, and the introduction thence of a Hamitic element into the riverain populations, which is still strongly marked.

SEX-TRANSFORMATION IN BIRDS.—Crowing hens have long been known, but the first case of the complete transformation of a hen which had laid eggs into a functioning male was described by Crew in 1923. Gatenby and Brambell (*Journ. of Genetics*, Vol. 14, No. 2) have added to the list of less complete transformations. They describe a white Leghorn hen which developed the comb and wattles and part of the behaviour of a male. This was accompanied by a great accumulation of fat on the viscera, together with the presence of testicular tissue. Apparently in birds such transformations only take place from the female, which is the heterozygous sex, to the male. The writers discuss the relation of such cases to the chromosome theory of sex determination. Cunningham (*Sci. Progress*, Jan. 1925) has also discussed the problem of the sex characters of birds in its general bearings on the Lamarckian theory and other questions. He refers to the condition in certain breeds of fowls in which the cocks are henny-feathered. Morgan showed that the castration of such cocks causes the development of the normal cock-feathering. Punnett suggested that the hen-feathered condition of the cocks in these breeds is due to the presence of a non-sex-linked factor which causes the testis to develop a hormone suppressing cock-feathering, which is normally produced only by the ovary. Cunningham proposes an explanation of this condition based on the assumption that non-disjunction of the sex chromosomes has taken place, so that in a heterozygous Sebright Bantam hen, the sex chromosomes would be WZZ and not WZ. The test of this hypothesis by examining the chromosomes would be extraordinarily difficult because of the large number and variable form of the chromosomes in the chick. Morgan considered that his castration experiments removed the necessity for a theory of sexual selection or Lamarckian inheritance to account for somatic sexual characters. Cunningham points out certain objections to this view and emphasises, for example, that the pad of a frog's foot is not merely a by-product of a hormone producing some other character, but is definitely related in position and structure to the use to which it is put.

OOGENESIS IN A CENTIPEDE.—S. D. King (Sci. Proc. Roy. Dublin Soc., xviii. pp. 29-36, 2 plates, Nov. 1924) records observations on oogenesis in *Lithobius forficatus*. Yolk-formation in the oocytes takes place by extrusion of particles (the fate of which has not yet been determined) from the central nucleolus, and later by fragmentation of the nucleolus, the particles of which, after proliferation, grow into the definitive yolk-spheres. The Golgi bodies and the mitochondria do not take any direct share in yolk-formation. The mitochondria are at first diffuse, but become concentrated in the early stages of growth, when they form in the oocyte several clusters, some of which proliferate very rapidly, giving rise to round bodies which are not comparable to the yolk-nuclei of ascidians or to the mitochondrial masses described in the oocytes of insects. Later the mitochondria become evenly distributed in the cytoplasm. The Golgi apparatus behaves in the usual way; in the youngest oocytes it is concentrated, but later spreads through the cytoplasm and breaks into fine granules.

SEASONAL CHANGES IN THE WATER OF PONDS.—Messrs. W. R. G. Atkins and G. T. Harris (Sci. Proc. Roy. Dublin Soc., 18, pp. 1-21, Nov. 1924) compare the seasonal changes in the heleoplankton of two fresh-water ponds with alterations in the solutes, and show that in each pond there is a vernal rise in P_H followed by a period of stagnation with lowered P_H. In one pond this condition persisted until the autumn, but in the other—Staddon reservoir—it was succeeded by a period of high alkalinity lasting until October. These changes are associated with the spring increase in plankton and the development of masses of floating algæ in the reservoir. In both ponds the supply of phosphate is exhausted in spring and this sets a limit to the further growth of algæ, but phosphate increases again in winter, partly by regeneration and partly by the inflow of water rich in phosphates. It is highly probable that lack of phosphate, rather than of nitrate or of ammonium salts, limits the plankton in fresh water as it does in the sea. The rapid increase in plankton in the spring is associated with the increase in light rather than in temperature.

CULTIVATING A PLANT "VIRUS" IN VITRO.—Peter K. Olitsky, of the Rockefeller Institute of New York, has a note in *Science* for December 26, pp. 593-4, which will attract the attention of plant pathologists. In experimental work with the mosaic disease of

tobacco, he has drawn about 0·01 c c. of the juice from infected plants, by careful technique with sterile pipette, etc., and inoculated this into a medium consisting of the fresh aqueous extract, prepared from carefully selected tomato plants free from mosaic. The medium then, in seven to ten days, showed "a faint, uniform, translucent, almost imperceptible haze." No microscopic technique revealed definite formed elements in the medium, but as the result of dilution by subcultural methods, the conclusion is reached that at dilutions far beyond that at which the original 0·01 c c of virus containing sap would still be active, successful inoculation of the disease could be achieved These results are particularly interesting as being obtained with the virus of tobacco mosaic, upon which Allard carried out his well-known experiments showing the filterable nature of the virus, and its highly resistant nature to heat and ordinary precipitants, etc The more detailed account of these experiments that is promised will be awaited with interest.

SILVER LEAF ON RHODODENDRONS.—Mr. A D. Cotton has a record in the *Gardeners' Chronicle* of February 14 of the appearance of silver leaf upon rhododendrons in cultivation in Great Britain. The characteristic silvering of the foliage is missing, but after removal of the dead and dying branches, fructifications of *Stereum purpureum* developed upon the stumps The disease seems to spread very slowly in the wood of the rhododendron, but there seems little doubt that in some of the cases observed by Mr Cotton the organism was acting as a parasite and responsible for the dying back of the branches. Now that attention has thus been directed to the attack, doubtless other growers of rhododendrons will pay special attention to signs of dying back of branches in rhododendrons.

VARIATION IN BLUE-GREEN ALGÆ.—In a paper on variation and species in Cyanophyceæ, Mr. W B. Crow (*Journ Genetics*, vol 14, No 3) describes observations and cultures of these organisms and draws a number of interesting conclusions. The cell structure in this group of unicellular and filamentous algæ is very simple, there being no true nucleus or karyokinetic division, and sexuality is also absent Mr. Crow correlates the continuous variation with these features The systematic differences are shown to be similar to those variations produced by changes of environment in cultures The characters of the group are regarded as belonging entirely to the kind called by Gates organismal, the absence of karyogenetic or Mendelian characters being correlated with the absence of nuclei and sexuality. Various parallelisms in variation with Isokontæ and other groups of algæ and fungi are also pointed out, and the general constancy of the forms when grown artificially is emphasised. Such studies are valuable for comparison with the genetics of higher organisms.

THE ORIGIN OF THE CYCADS.—English botanists, remembering the caution with which that veteran palæobotanist Dr. D H Scott now speaks, will read with some scepticism the confident pronouncement with which the address of Prof. C. J Chamberlain, chairman of Section G of the American Association for the Advancement of Science, commences (*Science*, January 23). Prof. Chamberlain is quoted as saying that "the widest gap in the evolution of plants used to be the one between the ferns and seed plants; but the researches of the past thirty years have bridged the gap so completely that the two groups are now separated only by the artificial definitions of the taxonomist." None is better qualified, however, than Prof. Chamberlain to discuss the salient features of structure and distribution in the Cycadales; and with reference to the deficiency of our knowledge of their fossil history, there will be general agreement that at the present day a study of distribution of a group in geological times may often be a study of the distribution of the enthusiastic and trained palæobotanist. In exemplifying this thesis Prof. Chamberlain pays a well-deserved tribute to the productive labours of the American palæobotanist Prof. Wieland.

SURVEY WORK IN NORTHERN CANADA.—The Topographical Survey of Canada is pushing its work farther north every summer and has parties at work in the barren lands and the northern islands of the Arctic Archipelago. Some notes in the Journal of the Dominion Land Surveyors Association by Mr. G. H. Blanchet give a preliminary account of the drastic changes in the map that accurate survey is making in regions relatively so accessible as the Great Slave Lake and the upper part of the basin of the Coppermine River and Backs River The position and extent of Lakes Clinton-Colden, Aylmer, Mackay and de Gras up to the present have figured on maps chiefly from hearsay reports. Last summer Dominion surveyors found them very much out of position and corresponding but little with previous notions. The party found the outlet of the upper Coppermine River from Lac de Gras, but was unable in the short season to go down the valley Another paper in the same publication notes the beginning of surveys in and around the new station of the Canadian Mounted Police in Ellesmere Land, Devon Island, and Ponds Inlet.

THE PROBLEM OF ATMOSPHERIC ELECTRICITY.—The issue of the *Physikalische Zeitschrift* for January 1 is a Jubilee number of 92 pages. It contains an account of the life and work of Georg Hirzel, by whom the *Zeitschrift* was planned and founded in 1899, with Profs Riecke and Simon of Göttingen as editors. The issue also contains an account by Dr. R. Seeliger of the report on the fundamental problem of atmospheric electricity made by Prof. Hans Benndorf to the meeting of the German Scientific and Medical Association at Innsbruck. The variation of electrical potential with height in the atmosphere and the electrical conductivity of the atmosphere itself imply a flow of electric current to the earth, which for the whole earth amounts to about 1000 amperes. To explain how this current is maintained has been the problem of atmospheric electricity for some years. It has, however, been reduced to insignificance by the larger problem raised by the measurements of Dr. L. A. Bauer, who finds that the lines of magnetic force on the earth's surface necessitate a current of about 3 million amperes. Prof Benndorf ascribes this current to β-rays from the sun too swift to produce ionisation of the atmosphere.

DIRECTIONAL QUANTIFICATION IN A MAGNETIC FIELD.—Prof. W. Gerlach describes, in the F. Paschen "Festschrift" of the *Annalen der Physik* published in January, an improved apparatus for studying spatial or directional quantification, and so measuring the magnetic moment of the atoms of metallic vapours. With copper, silver, and gold, the vapours of which are monatomic, the magnitude of the shift of the atomic stream in a magnetic field shows that they behave exactly as single quantum atoms, or more generally, as atoms with an apparent (effective) moment of one magneton, should do according to the theory. Thallium vapour is also monatomic, but the magnetic effect in this case is much smaller. There is no magnetic effect for lead or tin, though lead vapour

is monatomic and the same is probably true of tin vapour; this is partly due to the low temperature employed, though it was high enough in the case of tin to have enabled ±0·5 of a magneton to be observed. Bismuth and antimony vapours consist wholly or partly of molecules and multiple molecules; a definite theoretical explanation of the results is therefore impossible for these metals. Nickel vapour is monatomic, the experiments show that in the normal state the atom has a magnetic moment of several units; 0 and $\pm i$ magnetons (i about two) have been proved certainly, apparently there are also atoms with still higher moments. The result of the magnetic analysis is rather complicated, and it is hoped that it will be possible to obtain a more complete analysis of the plates for this metal. There were considerable experimental difficulties in the case of iron, and the appearances expected from a consideration of its spectrum could not be obtained in the plates.

THE X-RAY ABSORPTION BAND HEADS OF NICKEL AND OF ZINC.—A method of determining the wave length of an X-ray absorption band head is described by Dr. W Walter in the *Zeitschrift für Physik*, December 31. An X-ray tube is used, giving a line spectrum with numerous lines, one of which lies as near as possible to the wave length of the band head to be measured. When the X-rays are passed through screens made of the element to be investigated, lines corresponding to longer wave lengths than this show no absorption, while those corresponding to shorter wave lengths are strongly absorbed. In the case of nickel, the following table gives the estimated intensities of three lines, photographed directly, and after passing through nickel filters *b* and *c*

Line.	λ × 10¹¹ cm.	Intensity.		
		a	*b*.	*c*
$N_{1\beta}$ . . .	1497 03	10	10	10
$W_{\alpha'}$ . .	1484 52	8	5	2
W_{α} . . .	1473·48	50	8	1
Thickness of filter, mm. .	...	0·0000	0·0095	0·0163

$N_{1\beta}$ is not absorbed by nickel, since its wave length is greater than that of the band head, which according to Kossel's theory must have a wave length a little smaller than that of the Kγ line of nickel, 1485·4 × 10⁻¹¹ cm. The $W_{\alpha'}$ line satisfies this condition, and it will be seen that its behaviour agrees with its lying in the band head, since the relative change of intensity caused by the filters is considerably less than in the case of W_{α}, which lies well inside the absorption band. Duane and Hu give 1489·0 for the position of this band head, which is clearly much too large. Similar results were obtained for zinc, though in this case the X-ray tube employed gave no line which agreed so closely with the position of the band head as in the case of nickel. The difference between the value obtained and that of Duane and Hu is considerably greater for zinc than for nickel.

NEW SYNTHESIS OF UREA.—Dr. K. C. Bailey, in the Proceedings of the Royal Dublin Society, November 1924, describes a new synthesis of urea from carbon dioxide and ammonia. The mixed gases, preferably in the ratio 4 : 1, are passed at atmospheric pressure through the annular space between two concentric tubes, the outer, quartz, tube being heated to 500-700°, and the inner, glass, tube being kept water-cooled. The yield increases with temperature up to at least 700° C.

OXY-CELLULOSE.—In the Journal of the Textile Inst, vol 16, No. 1, January 1925, Constance Birtwell, Douglas A. Clibbens, and Bert P Ridge publish as Part I. of "The Chemical Analysis of Cotton" a comprehensive study of oxy-cellulose As the result of carefully controlled oxidation of cotton with mild oxidising agents, they are able to analyse the different results of such agents upon cotton cellulose, and they point out that two main types of oxy-cellulose should be distinguished. In one type, the product resulting from oxidation shows great affinity for methylene blue and high retentive power for alkalis; this type of oxy-cellulose is not chemically altered by boiling in dilute alkali. The other type of oxy-cellulose has enhanced reducing properties, best measured by the weight of copper reduced under standard conditions. This type loses entirely its chemical characteristics as an oxy-cellulose on boiling with dilute alkali, losing abnormally in weight at the same time; it is afterwards indistinguishable chemically from pure cotton cellulose, though the physical properties, *e g* tensile strength, may be altered Which type of oxy-cellulose is produced predominantly during the technical process of bleaching depends chiefly upon the acidity or alkalinity of the hypochlorite solution, on the alkaline side of the neutral point the product tends to be of the first type, with high absorption of methylene blue and low copper number, on the acid side the type with high reducing power is obtained.

FLOW AND RUPTURE OF METALS DURING CUTTING.—The report of the Cutting Tools Research Committee of the Institution of Mechanical Engineers, read on January 23 by Dr. W. Rosenhain and Mr A. C Sturney, contains an account of experiments made to determine the behaviour of material in the vicinity of the edge of the cutting tool, and is illustrated with several unique photomicrographs of cross sections taken through chips in process of formation. By using a simple type of cut and varying only two factors, namely, depth of cut and top-rake angle, certain definite regularities of behaviour have become manifest. According to the conditions of cutting, the separated metal takes the form of three distinct types of chip: (*a*) the "tear" type, in which rupture of the metal occurs by the formation, well in advance of the nose of the tool, of a tear or crack tending to run inwards from the periphery of the stock Since such a tear cannot progress very far, a succession of fresh starts are made by the tool, and the surface of the work is left in the form of rough projections, each of which probably corresponds to successive shearing of the chip. (*b*) When the conditions are changed by either reducing the depth of cut or increasing the top-rake angle, or both, the ultimate result is the formation of the "flow" type of chip. (*c*) Intermediate conditions produce an intermediate type called the "shear" type, since it is formed mainly by a process of shearing on a plane making an angle of roughly 30° with the direction of motion of the tool. So far as the present investigation goes, it indicates that the best results in cutting in regard to the removal of the maximum amount of metal per unit distance of tool travel, the least irregularity of surface, the closest agreement between intended and actual depth of cut, and the minimum wear of tool, are obtained by using a top-rake angle a very little smaller than that at which the heavily deformed zone before the nose of the tool just disappears, in conjunction with the greatest depth of cut which still allows the formation of the flow type of chip.

The Future of the Motor Ship.

By Engineer-Capt. EDGAR C SMITH, O.B.E., R.N.

THE introduction of the "Otto" cycle for gas-engines by Nicolas August Otto in 1876, the construction of the compact light spirit engine by Gottlieb Daimler in 1884, and the publication of his memoir, "The Theory and Construction of a Rational Heat Motor," by Rudolf Diesel in 1893, are three of the landmarks in the history of the internal combustion engine. The first led to a great extension in the use of gas-engines, the second paved the way for the motor car and aeroplane engine, while Diesel's work gave us the most efficient of modern heat engines. Just as the petrol engine has revolutionised transport by road, so the Diesel engine bids fair to revolutionise transport by sea. Otto died in 1891, Daimler in 1900, and Diesel was drowned in the North Sea in 1913, but each lived long enough to see his work bearing good fruit.

Diesel, who was born in Paris of German parents in 1858, was induced to take up the study of thermodynamics by von Linde, and ultimately assisted Linde in his work on refrigerators. He also worked in the shops of the well-known firm of Sulzer Brothers of Winterthur, and after completing his theoretical investigations was enabled to build an experimental engine. Many interesting details of his early work were given by Diesel himself to the Institution of Mechanical Engineers in 1912, but it was his account of a 20 H.P. engine communicated in 1897, which first attracted general attention, and it was then that, upon the advice of Lord Kelvin, a Scottish firm of engineers took up the manufacture of Diesel engines. Though, like the steam turbine of Sir Charles Parsons, it found its first useful sphere in the power-houses of the day, its application to ships was only a matter of time, and after being used in various craft, a Diesel engine was fitted in the *Toiler* by the Tyne firm of Swan, Hunter, and Wigham Richardson, and in 1911 that vessel crossed the Atlantic.

The *Toiler* was but a small vessel of 3000 tons carrying capacity and 360 horse power, but she was soon followed by the *Jutlandia* and *Selandia*, engined by Burmeister and Wain of Copenhagen, and then by the British vessels *Arum*, *Arabis*, and *Abelia*, all three of which were the victims of German submarines during the War. At the beginning of the War in 1914 there were nearly three hundred Diesel-engined ships afloat. The War, however, hindered progress in this direction, but during the last year or two much greater strides have been taken, and there are now nearly 2000 motor ships of a total tonnage of 2,000,000 tons, and about half the ships under construction to-day are designed for driving by Diesel engines. It is true this 2,000,000 tons is but about a thirtieth of the world's tonnage, but the facts are significant, and many consider that what the Americans have called the "Dieselisation of the sea" has definitely set in.

How the steam reciprocating engine and the steam turbine are being displaced can be seen from the following figures, gleaned from the returns of Lloyd's Registry of shipping, which show the tonnage classed each year and the types of machinery adopted.

Year	Steam Reciprocating Engine	Steam Turbine	Oil-engine
	Tons.	Tons.	Tons.
1918–19	2,633,570	1,051,302	75,934
1919–20	2,821,031	1,286,046	79,805
1920–21	2,373,067	754,513	101,608
1921–22	1,420,524	870,037	226,552
1922–23	842,358	603,037	165,229
1923–24	610,851	99,464	164,336

In view of these facts, especial interest attaches to the presidential address of Sir Westcott S. Abell, the chief ship surveyor of Lloyd's Registry, to the Institute of Marine Engineers, delivered on February 10, and to the lecture of Sir Fortescue Flannery to the Royal Society of Arts on the following day. "The Motor Ship in the Light of the History of Marine Propulsion" was the title of Sir Westcott Abell's address, while Sir Fortescue Flannery took as his subject "The Diesel Engine in Navigation." So firmly convinced are both authors that the Diesel engine is the ships' engine of the future, that the former remarked that "the disappearance of the steam-engine from overseas trade is largely a matter of time," while Sir Fortescue Flannery said that an examination of the figures "gives support to the belief that in a comparatively short time the Diesel engine will almost wholly displace the steam boiler at sea."

Though both containing the same conclusions, the two addresses were very different in character. Starting with the point of view that the Diesel engine has demonstrated its reliability—an essential feature in any marine engine—Sir Westcott Abell discussed what he termed the economic efficiency of the motor ship. At present, Diesel engines cost much more than steam machinery, and the cost of the oil per ton is enormously greater than the cost of coal per ton. But the reduction in the amount of fuel expended is so great that "with the present availability of and cost of oil fuel there is a distinct margin in profit in favour of the Diesel-engined ship compared with the coal-fired boiler and the steam-engined vessel." Sir Westcott's figures and diagrams illustrate this point, for with a ship of 8000 tons deadweight carrying capacity, the oil-engined ship can carry 10 per cent more cargo than the steamship. Discussing the mechanical and thermal efficiencies possible with modern machinery, Sir Westcott Abell comes to the conclusion that even with the heavy Diesel engine at present fitted, where only 5 B.H.P. is obtained for every ton of machinery, "the principal economic gain arising from the introduction of the Diesel engine has already been obtained." The problem now is "to devote considerable attention to obtaining the maximum simplicity, gaining thereby in reliability and ease of maintenance." Also, there are the auxiliaries, in which many improvements can be made. Among the diagrams illustrating the address is one showing the decline of the sailing-ship and the rise of the steamship, and it will be interesting to see if the Diesel engine supersedes the steamship in the same way.

The crowded lecture-room of the Royal Society of Arts and the gathering of distinguished shipowners, shipbuilders, and engineers on the occasion of Sir Fortescue Flannery's lecture were ample testimony to the importance of the subject. The interest of the occasion was increased by the presence in the chair of Lord Bearsted, the pioneer of the present-day system of carriage of petroleum in bulk in tank steamers. The lecture was a review of the introduction of the use of oil and the action of the Diesel engine, and contained explanations of the types of Diesel engines, of which there is a somewhat bewildering variety. Compared with a good steam plant, which uses about 1·8 lb. of coal or 1·4 lb. of oil per B.H.P. per hour, the Diesel engine burns about 0·4 lb. Apart from the saving in the fuel bill, a Diesel-engined ship can go farther afield or more cargo can be carried. All early motor ships had twin screws, but experience has shown the oil engine to be reliable and single screws are now being fitted where suitable. Sir

Fortescue Flannery dealt with the main points in the different designs of single-acting and double-acting, and of four-stroke and two-stroke engines such as the Burmeister and Wain, North British, Tosi, Vickers, Werkspoor, Doxford, Fullagar, Polar, and Sulzer, and also of that most interesting development, the Still engine, which is a Diesel engine and steam-engine combined. Developments are still proceeding with rapid strides towards the double-acting type and the consequent increase of power in proportion to the weight, but there is at present no approach to the standardisation such as is attained in the triple-expansion engine.

During the course of the evening, Lord Bearsted read a characteristic letter on the oil question from the late Lord Fisher, written in 1911, and he also gave some figures respecting the oil-engines suitable for a light cruiser. The cruiser, it is true, would have a speed of 26 knots as against a speed of 28 knots of her sister ship with steam machinery, but she would have a very much greater radius of action He seemed to think that the Admiralty has not done so much as it might to further the progress of the oil-engine for propulsion

In the discussion that followed, Engineer Admiral Sir Robert Dixon, the Engineer-in-Chief of the Fleet, recalled the work done in the Navy on the Diesel engines for submarines and referred to the experimental plant founded at West Drayton. Before an oil-engined battleship is feasible, however, the Diesel engine must give far more power for its weight than those in existence at present

It may be remarked that even the late Lord Fisher would scarcely have cared to command a light cruiser of 26 knots, even if fitted with oil-engines, when trying to overtake an enemy ship of the same class wth a speed of 28 knots In building the famous *Dreadnought*, a thousand tons in weight and 100,000*l.* in money were saved by the adoption of steam-turbine machinery, but there seems little prospect at present of doing anything similar by the adoption of Diesel engines in a man-of-war

The Effects of Posture and Rest in Muscular Work.[1]

THE problems of muscular activity have been investigated for many years from an academic viewpoint, yet it is only in recent times that a demand has arisen for the application of exact means of measurements of the physiological cost of muscular work in industry The Medical Research Council's report for the years 1923-24 states that "The studies of muscle function which were almost notorious for their supposed uselessness to the student or physician have laid down basic knowledge which now underlies many parts of medical science and art, and are beginning to remove empiricism from practical studies of physical training and of industrial labour"

The output of energy of an individual may be calculated by measuring the amount of oxygen and carbon dioxide present in the expired air, and from these data the physiological cost of the work can be assessed This method of estimating the "cost" of work or muscular activity places at our disposal a means of comparing the efficiency and capacity of the human machines under different conditions.

Two methods are available for the measurement of energy output—(*a*) direct and (*b*) indirect calorimetry The unit of measurement used is the large or kilo calory. In direct calorimetry the individual is enclosed in a special chamber so constructed that the heat given off is measured The apparatus is also arranged for the collection of the expired air, so that direct and indirect calorimetry may be combined

In indirect calorimetry the subject wears a mouth-piece fitted with two valves One valve serves for inspiration, while the other valve allows the expired air to pass down through a wide tube into a rubber bag, which the subject carries during the experiment The expired air can be drawn off and analysed in a Haldane apparatus. The ratio of carbon dioxide given off to oxygen absorbed can then be obtained, and from these data the heat units are calculated. If the measurements are carried out on the subject at rest and during work, an exact estimation can be made of the energy required for this particular task.

In a recent publication of the Industrial Fatigue Research Board on "The Effects of Posture and Rest in Muscular Work," Miss E. M. Bedale has investigated the energy expenditure of a woman carrying loads in different positions. Miss Bedale has used the indirect calorimetric method for estimating the physiological costs of the work. It is shown from the measurements made that the energy expenditure varies with the position in which the load is carried. The physiological cost of carrying with a yoke is low and involves less physiological disturbance than any other The experiments suggest that the continuous carrying of a load exceeding 35 per cent. of the body-weight is likely to cause rapid impairment of working capacity A series of photographs of the different modes of weight-carrying bring out the importance of the study of body posture. Some of the methods, if used continually, will rapidly lead to body deformities, with impairment of the normal physiological functions The use in industries of methods least injurious to the body would be an aid in the prevention of disease, and undoubtedly lead to greater efficiency The results of further investigations will be awaited with interest The data collected will tend to remove empiricism from studies of industrial labour, and will give a standard of measurement more accurate than that of output

Prof. E P Cathcart contributes a preface which deals in a clear and concise manner with methods of measurement, and points out the pitfalls which beset the investigator in work of this type

In the same publication, Dr H M Vernon gives the results of an investigation on "The Influences of Rest Pauses and Changes of Posture in the Capacity for Muscular Work" The conclusions drawn by Dr. Vernon suggest that the promotion of circulation plays an important part in the prevention of fatigue, the value of a rest pause being increased if the worker moves about during the interval. Postural changes during work are shown to be as necessary as rest pauses if efficient work is to be carried out

An interesting point is raised concerning the effect of additional movements during muscular work. The application of motion study to industrial processes has resulted in the elimination of many unnecessary movements and a marked increase in output The results now obtained suggest that the removal of too many unnecessary movements may be too drastic, and even better results might be obtained if a few extra movements, sufficient to promote circulation, were allowed. The proof of this suggestion will probably only be obtained by investigating each process separately by the old method of trial and error

Report No. 29: "The Effects of Posture and Rest in Muscular Work: (*a*) Comparison of the Energy Expenditure of a Woman carrying Loads in Eight Different Positions," by E. M. Bedale; (*b*) "The Influence of Rest Pauses and Changes of Posture on the Capacity for Muscular Work," by Dr. H. M. Vernon. Pp. 35. (London: H.M. Stationery Office, 1924.) 2*s.* 6*d.* net.

University and Educational Intelligence.

BRISTOL.—Last year the Council set aside a portion of a bequest from the late Mr. H. H Wills for the purpose of providing additional staff and equipment in the Department of Physics when the erection of the Henry Herbert Wills Physics Laboratory is completed. Though the building is not yet ready for occupation, it has been decided to create a readership in mathematical physics as from August 1, and Dr. J. E. Jones has been appointed the first reader.

CAMBRIDGE —Mr. Ll. H. Thomas, Trinity College, and Mr H. Horrocks, St Catherine's College, have been elected to Isaac Newton Studentships in astronomy and physical optics.

EDINBURGH —At the meeting of the University Court on Monday, February 16, a letter was read from Sir Richard Lodge intimating his resignation from the chair of history as from the end of the current academical year. The Principal expressed great regret on behalf of the Court In Sir Richard Lodge the University had an ornament of whom it was proud and an invaluable helper in every branch of University activity His departure would be a severe loss not only to the School of History, which owed its present high reputation to his unremitting efforts, but also to the whole University, to the interests of which he had devoted his great abilities during a period of more than twenty-five years

Mr W. Oliver was appointed to be the first occupant of the chair of the organisation of industry and commerce, which was founded by a recent Ordinance of the University Court.

It was intimated that the Senatus had unanimously resolved, on the recommendation of the Faculty of Medicine, to award the Cameron Prize for the year 1925 to Prof R. Magnus, the Royal University, Utrecht, Holland This prize, of the value of about 200*l*., is awarded annually to a person who in the course of the five years immediately preceding has made a highly important and valuable addition to practical therapeutics.

The resignation, as from September 30, of Mr W. L Ferrar, lecturer in mathematics, on his election to a tutorial fellowship at Hertford College, Oxford, was accepted.

LEEDS —Dr. T. Wardrop Griffith has placed before the Council of the University his resignation of the professorship of medicine

Prof. T Wardrop Griffith was appointed to the chair of anatomy in 1887 and transferred to the chair of medicine in 1910 He began work in the old Medical School in Park Street and took an active share in the construction of the new School in Thoresby Place, in which he established one of the best anatomical departments in Great Britain.

OXFORD.—There will be an election at Keble College on March 16, on the results of an examination, to a Natural Science Scholarship on the Gibbs Foundation, of the value of 80*l*. per annum. Candidates must be more than twenty years of age on March 16, and if already members of the University, of not more than two terms of University standing on that day. By the terms of the benefaction, the scholarship is tenable only by members of the Church of England. Inquiries should be addressed to Mr. G. D. Parkes, at Keble College, on or before March 2.

SHEFFIELD —Applications are invited for the chair of mining They should be sent to reach the registrar by, at latest, March 31.

DR. W. HIEBER, of Würzburg, has been appointed director of the department of inorganic chemistry at the University of Jena.

A NUMBER of scholarships in connexion with Bedford College for Women, Regent's Park, N.W.1, are being offered, particulars of which are obtainable from the principal.

APPLICATIONS are invited for two posts at Auckland University College, New Zealand, namely the professorship of forestry and a lectureship in civil engineering. Particulars may be had from the High Commissioner for New Zealand, 415 Strand, W.C.2.

THE Leathersellers' Company's Technical College, 176 Tower Bridge Road, S.E.1, invites applications for the post of chemical lecturer and demonstrator. Candidates must possess a good science degree, but a knowledge of leather is not essential.

THE annual general meeting of the Association of Technical Institutions will be held at the Institution of Mechanical Engineers, Storey's Gate, London, on Friday and Saturday, March 6 and 7. The proceedings will commence with a reception by the acting president, Mr. W. H Patchell, which will be followed by the presidential address of the president elect, the Right Hon. Lord Montagu of Beaulieu. Friday afternoon and Saturday morning will be devoted to the consideration of business matters and the reading of papers by The Right Hon Lord Emmot and Principal W. M. Varley, on "The Local College and its relation to surrounding Education Authorities", Mr. G. Mavor, Head of the Department of Continuative Education, Loughborough College, on "Training and Education for Apprenticeship", Mr. J. E Montgomrey, assistant secretary of the Institution of Mechancial Engineers, on "The Working of the Schemes for National Certificates and Diplomas in Engineering" Sir John Dewrance is entertaining members of the Association and others attending the meeting to luncheon on Friday, March 6, at the Trocadero Restaurant.

THE Royal Technical College, Glasgow, has received a gift of 50,000*l*. from an anonymous donor, who has given the governors of the College complete freedom to expend the revenue derived from it as they may see fit. The industrial depression in the south-west of Scotland, particularly severe in the engineering, shipbuilding, and iron and steel industries, with which the College is closely associated, has resulted not only in a diminution in the number of local students, although it has still double the number of the regular students of session 1913–14, but also there has been less capacity on the part of the industries to give financial support to the College. There is little doubt that the wise and far-seeing policy of the late Sir George Beilby, who was chairman of the governors for many years and the guiding spirit in the remarkable development of the College, both in its teaching organisation and the provision made for research work, has led the anonymous donor to consider the College worthy of this most welcome addition to its resources. Sir George Beilby's connexion with the College is to be marked by the foundation of a memorial medal in technical chemistry and by the generous gift by Lady Beilby of his excellent organ, which is to be reconstructed and placed in the College hall. Other recent donations are the continuance by the Bellahouston Trustees for another three years of an annual grant of 1000*l*. which they have given during the past five years, and substantial additions to the electrical engineering equipment in the form of modern machines presented by about twenty leading British firms of electrical engineers.

Early Science at Oxford.

February 29, 1683/4. Dr. Wallis was pleased to inform us, that ye way commonly used in opening frozen pumps, with salt, has been known to make pumpwater, under his house, apt to curdle in boiling, and unfit for washing, which naturally is fit for use, and bears soap very well; but ye water probably will recover itself as soon as ye salt shall be drawn off.

Dr. Pit acquainted ye Society, that sallet oyl cannot be made to boyl over; this has been observed by late experiments, and will give some light to that custom of ye sugar boilers, who used to throw a piece of sewet, candle, etc into their sugar; and by these means keep it from boiling over

Some Queries concerning the splitting of Trees by ye late great frost, were brought in by Dr. Plot. they are as follows:—Whether any of these trees have split with a noise? Whether they are split quite through, or only on one side? Whether they are all split to ye same point of ye Compass? Whether ye splitting be more common in ye Trunk, or in ye Boughs? Whether any Ice has been found in ye vessels of ye wood? Whether ye trees split be any of them dead? Whether any of ye trees split have closed since ye thaw? Whether ye Bark be loosned by ye splitting, from ye wood?

Dr. Wallis mentioned vast numbers of dead Congers, which were thrown up by ye sea, at Dim-Church wall, along ye coast of Kent, during the late hard frost, as also about eight years ago, the same was observd on ye Severn shore in Somersetshire, about twenty years ago

March 1, 1686/7. Upon mentioning of Mr. Hooke's Discourse about the changes which he supposes to have been made upon the surface of the Earth, Mr President observed that the latitude of Oxford is not sensibly altered in these four hundred or five hundred years last past, as appears by the Alphonsine Tables and some MSS. in Oxford, in which though there may be about one minute more, or one minute less than ye present latitude, yet that may well be attributed to the unaccurateness of the observations. —It was stated at this meeting that the age of one Mother George, now living in Oxford, is about one hundred and eleven years.

March 2, 1685/6. Dr. Plot shewed ye Society two Swedish Runestocks or Primestocks, and one book almanack; also severall old English almanacks, of which some were for families, others for private persons; some of brasse, others of wood, all perpetuall.

March 3, 1684/5. Mr. Leigh gave a farther account of ye Balsamic Earth It will take fire at a candle, and, if tost in ye air, will burn exactly like a torche, an oyl dropping from it scarce distinguishable from ye oyl of amber Any other earth whatsoever, if put into ye place, where this is dug, will in a year's time be exactly the same with this. 4 drops of this oyl is a present Cure for ye Colic, and may therefore in all probability be proper in those distempers, which affect the nerves

A letter from Mr. John Aubrey, dated London Feb. 27, mentioned an opinion that some merchants were of; that beasts are generally offended at a Barbary Lion's skin. There being one of these skins in ye Musæum Ashmolianum, he desires, ye truth of this matter may be enquired into, which was ordered to be done.

March 6, 1687/8. An account was delivered of what appeared to Mr. Pit upon the dissection of a *dog*, that had Mercury injected into one of the jugulars. The mercury was thrown out of the blood into the cavity of the abdomen, as likewise some appearance of it in the other cavitys of the body.

Societies and Academies.

LONDON.

Royal Society, February 19.—O W **Richardson** and A. F. A **Young**: The thermionic work-functions and photoelectric thresholds of the alkali metals The photoelectric threshold for normal potassium is close to 7000 Å U, which agrees with the known wavelength of maximum activity λ_{max} and the equation $\lambda_0 = \frac{3}{2}\lambda_{max}$ Uncertain traces of a thermionic threshold agreeing with this have been found at about 200° C. in one experiment, but the thermionic thresholds usually effective at this and lower temperatures are of a much lower magnitude, even under the best vacuum conditions. A common thermionic threshold effective at about 200° C. corresponds to λ_0 = about 10,000 Å U A photoelectric emission with this infra-red threshold has been got by exposing potassium to a luminous discharge in hydrogen or water vapour This may be due to the growth of small patches normally present. There is no evidence of photoelectric activity further out in the infra-red, although there is a thermionic threshold which corresponds to $\lambda_0 = 30{,}000$ A U The glow discharge not only brings out undeveloped thresholds, but it also augments the normal emission.—J H **Brinkworth** On the measurement of the ratio of the specific heats using small volumes of gas The quantity actually measured is the cooling effect in adiabatic expansion, *i.e.* the ratio of the drop in temperature to the drop in pressure These two quantities are measured directly, the former by using a suitable platinum thermometer, and the latter from the readings on an oil gauge The values of the ratio of the specific heats thus experimentally obtained are used for the calculation of the specific heats of air and of hydrogen The specific heat of air at constant pressure is practically constant, and equal to 0·2395 cal /gm °C over the temperature range 155° to 290° A The molecular heat of hydrogen falls rapidly from 4·88 at 290° A. to 3·30 at 90° A None of the theoretical curves representing the variation in the molecular heat of hydrogen agrees with the experimental curve, the divergence, at some temperatures, being certainly five times greater than an outside estimate of the inaccuracy of the experimental results.—F H **Constable**: The catalytic action of copper. Part VI Chemical reaction occurs only when an alcohol molecule is adsorbed over a characteristic arrangement of copper atoms, called a reaction centre. There is a large variation in the number of atom centres lying beneath one adsorbed alcohol molecule on various crystal faces thus the reaction centre density varies also. The activity of the surface is controlled by the exponential activation factor, and by the reaction centre density on the surface.—Part VII The rate of dehydrogenation of ethyl and butyl alcohols has been studied at pressures from 10 cm of mercury to two atmospheres. The reaction velocity was found to be independent of the pressure.—V. H **Stott**, Edith **Irvine**, and D. **Turner**: Viscosity measurements with glass. For the range 10^8 to 10^{17} poises, the apparatus is a modification of the method of Trouton and Andrews, in which the resistance to torsion of a circular rod is determined This apparatus may be readily modified so as to extend its applicability down to 10^4 poises. Measurements of lower viscosities down to about 10^2 poises depend on determinations of the rate of fall through the glass of a partially counterpoised iridio-platinum ball. Temperature uniformity in the latter case has been achieved by the use of an electrically heated "black body" furnace possessing novel features.—W. G. **Palmer** and F. H.

Constable: The catalytic action of copper, Part V. The reaction velocity-temperature curves for ethyl, *n*-propyl, butyl, *iso*butyl and *iso*amyl alcohols (which have in common the grouping $-CH_2OH$) are identical within the limits of experimental error. This identity involves also the equality of the temperature coefficients and of the heats of activation. The higher alcohols caused rapid "poisoning" of the catalyst, but this secondary effect was circumvented.—P. A. M. **Dirac**: The adiabatic invariance of the quantum integrals. The postulate of the existence of stationary states in multiply periodic dynamical systems requires that if the condition of such a system, when quantised, is changed in any way by the application of an external field, or by the alteration of one of the internal constraints, the new state of the system must also be correctly quantised. It follows that the laws of classical mechanics cannot in general be true, even approximately, during the transition. During the so-called adiabatic change, which takes place infinitely slowly and regularly, so that the system practically remains multiply periodic all the time, classical laws may be expected to hold. In this case the quantum numbers cannot change, and it has been possible to deduce from the classical laws that the quantum integrals remain invariant.—D. L. **Watson**: The thermal decomposition of derivatives of oxalacetic ester: a unimolecular reaction. The decomposition, on heating, of derivatives of oxalacetic ester into a malonic ester derivative and carbon monoxide obeys the unimolecular (or simple probability) law, $dx/dt = k(a - x)$, and the velocity is uninfluenced by diluting with solvents or adding acidic substances, though retarded by high concentration of carbon monoxide. None of the substances could be stimulated to react by light of wave-length predicted from the Lewis-Perrin theory, or by ultra-violet radiation, which they absorb very strongly. They had energies of activation between 33,000 and 36,000 calories, and an "active life" of the order of 10^{-14} second, in agreement with many other first-order changes. The velocity of decomposition of phenyl-oxalacetic ester, however, was proportional to the amount of phenyl-malonic ester formed by the change (except when the latter substance was present in excess). This law, characteristic of simple reactions in pure liquids, may be explained by the hypothesis of "reflex activation," namely, that highly energised products of reaction are largely responsible for formation of fresh "active" molecules. Here, as in all known unimolecular reactions, two species of molecules evidently take part in the change.—K. R. **Rao**: (1) On the fluorescence and channelled absorption of bismuth at high temperatures. The absorption spectrum has been photographed at temperatures of the order of 1500° C. Some of the absorption bands in the visible region exhibit distinctly a fine structure, showing that these are due to the triple quantification. The vapour emitted a fluorescent radiation, and the fluorescent banded spectrum ranging from λ6570-λ5040, containing about 20 bands, shaded towards the red, has been photographed. This banded fluorescent spectrum indicates probably that the critical potentials of elements which are polyatomic are related to the molecule and not to the atom.—(2) A note on the absorption of the green line of thallium vapour. The green line of thallium consists of an intense central doublet accompanied by two satellites. Absorption by a column of non-luminous vapour indicates complete absorption of the central doublet at about 800° C., at which temperature the satellite was but very feebly absorbed. The total absorption of the satellite took place at about 950° C.—B. F. J. **Schonland**: The passage of cathode rays through matter. Cathode rays of velocities up to 0·55 that of light (100,000 volts) in quantities easily measurable on a galvanometer, were produced. These rays have been used to extend measurements of cathode-ray absorption to the β-ray region. The difference in variation of apparent absorption with velocity for different elements depends upon the fact that this is not a true absorption, since it includes the effect of the scattering back of rays on the side of incidence. The existence of a range for these rays has been established, and the values found for ranges at various velocities in aluminium are in close agreement with those calculated on Bohr's theory of absorption, which has now been tested from $\beta = 0{\cdot}20$ to $\beta = 0{\cdot}90$, with rays of penetrating power varying in the ratio of 1 to 5000. Cathode-ray absorption is due to gradual loss of energy of moving particles by collisions with electrons in matter. An examination of the principles underlying Bohr's theory of absorption shows that interchange of energy in such collisions must take place more freely than the usual conceptions of atomic structure allow. Absorption of cathode rays of various speeds by atoms of a given element does not appear to show any discontinuities corresponding to those observed in X-ray spectra.

PARIS

Academy of Sciences, January 19.—The president announced the death of L. Maquenne, member of the section of rural economy.—Maurice **de Broglie** and Jean **Thibaud**: The exceptionally intense absorption of a radiation by the atom which has just emitted it.—Maurice **Lugeon**: Fluvial erosion. Example of the Rio Negro in Uruguay.——**Calichiopulo**: The harmonic law of distribution of the errors of observation.——**d'Ocagne**: Remarks on the preceding communication.—Enea **Bortolotti**: Extension of the Beltrami-Enneper theorem to conjugated networks from V_2 to V_3.—D. **Mordouhay-Boltovskoy**: The primary factors of the integral function.—J. **Dufay** and A. **Couder**: The photometric study of the total eclipse of the moon of August 14, 1924. This eclipse was observed in a clear sky at Saint-Geniez (Basses-Alpes, 1070 metres). At 10′ from the centre of the shadow the stellar magnitude of the moon was, in red light ($\lambda = 0{\cdot}61\mu$), −2·8 in October 1921, and −1·3 in August 1924.—J. H. **Shaxby**: The diffusion of particles in suspension. As spheres of uniform size the cocci of the pyogenes staphylococcus were utilised, suspended in water. The value of the Avogadro number deduced from the experiments was 59×10^{22}.—Beaulard **de Lenaizan** and J. **Granier**: The specific inductive capacity of ice. The value 2·17 was found for the specific inductive capacity of ice, at a temperature of −4·5° C., and with a wave-length in air of 363·2 cm.—Marcus **Brutzkus**: A new mode of production of chemical reactions.—D. K. **Yovanovitch** and J. **d'Espine**: The magnetic spectrum of the high-velocity β-rays of thorium B+C. Seven of the high-velocity β-rays measured by L. Meitner are confirmed: three additional rays have been detected for which $H\rho = 6800$, 18,000, and 40,000. These new rays are very faint.—Henry **de Laszlo**: The absorption of ultra-violet rays by the methyl derivatives of naphthalene. The absorption spectra of α- and β-methylnaphthalene, 2 6-dimethylnaphthalene and 2,7-dimethylnaphthalene were measured, and the results are given on a diagram.—P. **Vaillant**: The law of variation with temperature of the (electrical) conductivity of solid salts and its possible relations with the characteristic spectrum of the metal of the salt.—Mme. Pierre **Curie**: The estimation of radium in uranium minerals containing tantalum, niobium, and titanium. The mineral is mixed with barium sulphate, fused with

potassium bisulphate, extracted with water and filtered. The precipitate on the filter is treated with dilute hydrofluoric acid. The insoluble portion containing the radium is boiled with sodium carbonate, to convert the barium and radium into carbonates, and the latter dissolved in dilute hydrochloric acid. After concentration to ice, the emanation is removed by a current of air and estimated in the usual manner.—Mlle Suzanne **Veil**: The evolution of the hydrate of nickel sesquioxide in the presence of water.—André **Charriou**: The use, in catalysis, of alumina which has absorbed various other substances. The decomposition of ether at 250° C. in the presence of alumina was studied. With one exception, the blue oxide of tungsten, the presence of foreign substances (SO_3, P_2O_5, CuO, CaO, CoO) reduced the catalytic power of the alumina in this reaction.—G. **Dubar**: The formations of the Lias and the upper Jurassic in Asturia.—L. **Eblé** and J. **Itié**: The values of the magnetic elements at the station of Val-Joyeux (Seine-et-Oise) on January 1, 1925.—L. **Blaringhem**: The production of new hybrids between the wild species of Triticum and the principal cultivated wheats. Analysis of their affinities.—A. **Guilliermond**: The instability of forms and the permanence of the mitochondria.—P. **Delauney**: The glucosides of several species of native orchids.—Emile F. **Terroine** and Jean **Roche**: Heat production and respiration of the tissues *in vitro* in the homeotherms.—A. F. **Roffo**: The action of the Röntgen rays on cholesterol. Cholesterol, in solution, is destroyed by the action of the X-rays, but the crystallised alcohol is unchanged by this treatment.—Edouard **Chatton** and André **Lwoff**: The etiology and structure of the Spirophyra. Their relationship with the Fœttingeria. The origin and evolution of the parasitism of these infusoria.

VIENNA

Academy of Sciences, December 11.—H. **Pettersson**: Communication from the Radium Institute, No. 173. On the reflection of α-particles from atomic nuclei, α-particles were scattered through nearly 180° by five different elements. With three of these elements, which are known to be disintegrated, no reflected α-particles were observed, even at ranges considerably smaller than those calculated by the collision-theory. With two heavier elements α-rays were observed, but with much smaller ranges than would correspond to an elastic collision. Possible explanations are given on the assumption that the α-particle penetrates into the nucleus. H-particles were detected after bombarding nickel and copper with α-particles.—H. **Handel-Mazzetti**: New Chinese plants (30th communication). An index list of some 100 descriptions published during 1924 is given.—J. **Albrecht**: Palæontological and stratigraphical results of the journey of Dr. Ampferer and Dr. Hammer in Western Serbia in the year 1918.—M. **Kohn** and S. **Strassmann**: Ninth communication on bromophenols, bromo- and bromo-nitro-phenols.—M. **Kohn** and R. **Marberger**: Tenth communication on bromophenols. On chloro-nitro-ether and bromo-nitro-ether of hydroquinone and of tolu-hydroquinone and the mobility of the halogen atom in the same.—M. **Kohn** and S. **Grim**: Eleventh communication on bromophenols. Bromination of hydroquinone-monomethyl-ether and of nitro-hydroquinone-dimethyl-ether.

Annual Report of the Director, United States Coast and Geodetic Survey, to the Secretary of Commerce, for the Year ended June 30, 1924. Pp. iv+80+21 plates. (Washington: Government Printing Office.) 10 cents.

Diary of Societies.

SATURDAY, FEBRUARY 28

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: The Counting of the Atoms (1.)

HULL ASSOCIATION OF ENGINEERS (at Technical College, Hull), at 7.15.—E. S. Rayner: Road Passenger Transport.

MONDAY, MARCH 2

CAMBRIDGE PHILOSOPHICAL SOCIETY, at 4.30.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.—General Meeting.

SOCIETY OF ENGINEERS (at Geological Society), at 5.30.—R. I. Money: *Notes on Preparing a Tender*.

ROYAL SOCIETY OF MEDICINE (Tropical Diseases and Parasitology Section), at 5.30.—Dr. H. E. Meleney: Kala Azar in China, with special reference to its Histo-pathology in Experimentally Infected Hamsters.

INSTITUTION OF ELECTRICAL ENGINEERS (Western Centre) (at South Wales Institute of Engineers, Cardiff), at 6.—L. Breach and H. Midgley: Drive of Power Station Auxiliaries.

INSTITUTION OF MECHANICAL ENGINEERS (Graduates' Section, London) (Annual Lecture), at 7.—W. H. Patchell: A Visit to America.

ARISTOTELIAN SOCIETY (at University of London Club), at 8.—J. H. Harley: The Theory of the State.

ROYAL SOCIETY OF ARTS, at 8.—Dr. W. Rosenhain: The Inner Structure of Alloys (III.) (Cantor Lectures).

SOCIETY OF CHEMICAL INDUSTRY (London Section, jointly with the Institute of Chemistry (London Section)) (at Chemical Society), at 8.

INSTITUTION OF THE RUBBER INDUSTRY (London Section) (at Engineers' Club, Coventry Street, W.), at 8.—F. Jones: Standardised Rubber-ware.

ROYAL SOCIETY OF MEDICINE (Epidemiology, Comparative Medicine, and Disease in Children Sections), at 8.—G. P. Male, Dr. M. J. Rowlands, Dr. Stanhouse Williams, Dr. David Nabarro, Sir Layton Bienkinsop, and others: Special Discussion: The Control of Tuberculosis and the Milk Supply.

INSTITUTE OF CHEMISTRY (Manchester Section).—Dr. A. Renshaw: Chemical Poisoning occurring amongst Industrial Workers.

TUESDAY, MARCH 3

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.15.—Prof. J. Barcroft: The Colour of the Animal Creation (IV.). The Colour of Fish.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—E. Banks: Variation in the Colours of European Birds in relation to the Conditions under which they live.—O. Thomas, M. A. C. Hinton, and Capt. G. C. Shortridge: On Mammals collected in 1923 by Capt. Shortridge during the Percy Sladen and Kaffrarian Expedition to South-West Africa. With Field-notes by the Collector.—Dr. C. F. Sonntag: A Monograph of *Oxyuropus ater*. I. Anatomy except the Nervous System, Skin, and Skeleton.—Mary L. Hett: A New Species of Temnocephala (Trematoda) from West Australia.—V. S. Vinogradov: The Structure of the External

Genitalia in the Rodents Dipodidæ and Zapodidæ as a Classificatory Character.—A. Loveridge: Notes on East African Scorpions and Solifugæ.

INSTITUTE OF MARINE ENGINEERS, at 6.30.—E. W. L. Nicol: Fuel Economy.

INSTITUTION OF ELECTRICAL ENGINEERS (East Midland Sub-Centre) (at Loughborough Technical College), at 6.45.—R. C. Clinker: The Constants of an Electric Circuit.

INSTITUTION OF ELECTRICAL ENGINEERS (North-Western Centre) (at Engineers' Club, Manchester), at 7.—Major E. I. David: Electricity in Mines.

INSTITUTE OF METALS (Birmingham Section) (at Chamber of Commerce, Birmingham), at 7.—J. H. Russell: Slags and Fluxes, their Composition and Uses.

INSTITUTION OF AUTOMOBILE ENGINEERS (Coventry Centre) (at Broadgate Café, Coventry), at 7.15.

INSTITUTE OF METALS (North-East Coast Section) (at Armstrong College, Newcastle-on-Tyne), at 7.30.—A. G. Lobley: Electric Furnaces.

HULL CHEMICAL AND ENGINEERING SOCIETY (at Grey Street, Hull), at 7.45.—Dr. W. M. Cramp: Pneumatic Transport of Materials.

RÖNTGEN SOCIETY (at British Institute of Radiology), at 8.15.—Dr. L. A. Levy and D. W. West: The Photometry of Fluorescent Screens.

WEDNESDAY, MARCH 4.

ROYAL SOCIETY OF MEDICINE (Balneology and Climatology, Epidemiology, Medicine, Therapeutics and Pharmacology Sections), at 5.30.—Dr. W. Edgecombe, Dr. J. A. Glover, Sir William Willcox, Dr. P. Hamill, Dr. Ackerley, Dr. Middleton, Dr. Kerr Pringle, Sir Percy Bassett Smith, Dr. R. Hill, J. E. R. McDonagh, Dr. Oliver Heath, Dr. C. E. Sundell, and Dr. Higgins: Special Discussion on The Nature, Prevention, and Treatment of Fibrositis.

THE NEWCOMEN SOCIETY (for the Study of the History of Engineering and Technology) (in Prince Henry's Room, 17 Fleet Street, E.C.), at 5.30.—C. E. Greene: Gun Handicraft.

INSTITUTION OF ELECTRICAL ENGINEERS (Wireless Section), at 6.—D. Dye: Current Transformer Methods of Producing Small Known Voltages and Currents at Radio Frequencies for Calibrating Purposes.—Lieut.-Col. K. E. Edgworth and Lieut. G. W. N. Cobbold: The Measurement of Frequency and Allied Quantities in Wireless Telegraphy.

INSTITUTION OF HEATING AND VENTILATING ENGINEERS (at Engineers' Club, Coventry Street, W.), at 7.—H. W. Bannister: Water Softening in relation to Heating and Domestic Hot Water Supplies.

ROYAL MICROSCOPICAL SOCIETY (Biological Section), at 7.30.

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at Chemical Society), at 8.—G. Van B. Gilmour: A New Method for the Determination of Butter Fat.—R. C. Frederick: The Investigation of Ventilation Conditions.—R. C. Frederick and E. R. Webster: A Simple and Self-contained Spectroscope Lighting Unit.—P. K. Frohlich: The Carbon Error in the Quantitative Deposition of Nickel and Iron from Complex Oxalate Electrolytes.

ROYAL SOCIETY OF ARTS, at 8.—Prof. W. E. S. Turner: The Modern Production of Sheet Glass.

ENTOMOLOGICAL SOCIETY OF LONDON, at 8.

MEDICAL SOCIETY OF LONDON, at 9.—Sir Bernard Spilsbury: Wounds and other Injuries (II.) (Lettsomian Lectures).

THURSDAY, MARCH 5.

ROYAL SOCIETY, at 4.30.—Sir Arthur Schuster: The Life Statistics of Fellows of the Royal Society.—Prof. G. I. Taylor and Miss C. F. Elam: The *Plastic Extension and Fracture of Aluminium Crystals*.—A. Fage: An Experimental Study of the Vibrations in the Blades and Shaft of an Airscrew.—J. H. Vincent and A. L. Beak: Experiments on the Effects of Resistance in the Oscillating Circuit of a Triode.—*To be read in title only*.—Prof. G. H. Hardy: The Lattice Points of a Circle.—Prof. H. M. Macdonald: The Transmission of Electric Waves around the Earth's Surface.—R. M. Wilmotte: The Field of Force near the Neutral Point produced by Two Equal Coaxial Coils with special reference to the Campbell Standard of Mutual Inductance.—W. R. Dean: The *Theory of Elastic Stability*.—R. A. Frazer: *The Motion of Circular Cylinders in a Viscous Fluid*.

LINNEAN SOCIETY OF LONDON, at 5.—G. C. Robson: (*a*) Seriation and Symmetry in the Cephalopoda; (*b*) Exhibition of *Opisthoteuthis depressa* (Mollusca).—K. H. Barnard: Revision of the Family Anthuridæ (Isopoda) with Remarks on certain Morphological Peculiarities.—C. C. Lucatta: (*a*) Some Critical Species of Marrubium and Ballota; (*b*) Two Rare Spanish Species of Echium.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. S. MacNalty: *Epidemic Diseases of the Central Nervous System* (Milroy Lectures) (I.).

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.15.—Sir Arthur Smith Woodward: Dinosaurs.

ROYAL AERONAUTICAL SOCIETY, at 5.30.—Lt.-Col. C. B. Heald: Some Medical Aspects of Air Transport.

ROYAL SOCIETY OF MEDICINE (Balneology and Climatology, Epidemiology, Medicine, Therapeutics and Pharmacology Sections), at 5.30.—Dr. W. Edgecombe, Dr. J. A. Glover, Sir William Willcox, Dr. P. Hamill, Dr. Ackerley, Dr. Middleton, Dr. Kerr Pringle, Sir Percy Bassett-Smith, Dr. R. Hill, J. E. R. McDonagh, Dr. Oliver Heath, Dr. C. E. Sundell, and Dr. Higgins: Special Discussion on The Nature, Prevention, and Treatment of Fibrositis.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—F. C. Richards: Art in the Schools.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—Col. T. F. Purves: The Post Office and Automatic Telephones.

SOCIETY OF CHEMICAL INDUSTRY (Bristol Section) (at Bristol University), at 7.30.—M. W. Jones: Paint and Paint Making (Chairman's Address).

CHEMICAL SOCIETY, at 8.—I. J. Faulkner and Prof. T. M. Lowry: Studies of Dynamic Isomerism. Part XVII. The Mutarotation of Aluminium Benzoylcamphor.—Prof. T. M. Lowry: Studies of Dynamic Isomerism. Part XVIII. The Mechanism of Mutarotation, and of Hydrolytic and Prototropic Change; with a criticism of Baker, Ingold, and Thorpe's Doctrine of Non-intervention.—Prof. T. M. Lowry and E. M. Richards: Studies of Dynamic Isomerism. Part XIX. Experiments on the Arrest of Mutarotation in Tetramethylglucose.

ROYAL SOCIETY OF MEDICINE (Obstetrics and Gynæcology Section), at 8.—Dr. J. S. Fairbairn and Dr. Z. Mennell: Toxæmia in Early Pregnancy with Jaundice, Hyperemesis and Multiple Neuritis.—E. Williams and Dr. R. Reynolds: A New Method of Determining the Patency of the Fallopian Tubes by means of X-rays.—Dr. S. Forsdike: Investigation of the Uterus and Fallopian Tube by Inflation with Air and X-rays.

SOCIETY OF DYERS AND COLOURISTS (West Riding Section).—Prof. F. G. Donnan: Colloids.

FRIDAY, MARCH 6.

ASSOCIATION OF TECHNICAL INSTITUTIONS (Annual Meeting) (at Institution of Mechanical Engineers), at 11 A.M.—Lord Montagu of Beaulieu: Presidential Address.

ROYAL SOCIETY OF ARTS (Indian Section), at 4.30.—Sir Henry Sharp: The Development of Indian Universities.

ROYAL ASTRONOMICAL SOCIETY (Geophysical Discussion), at 5.—Prof. S. Chapman: Magnetic Phenomena in Polar Regions.

PHILOLOGICAL SOCIETY (at University College), at 5.30.—C. T. Onions: Dictionary Evening.

SOCIETY OF CHEMICAL INDUSTRY (Manchester Section, jointly with the Liverpool Section) (at 16 Mary's Parsonage, Manchester), at 7.—Dr. A. Schædler: Chemical Constitution and Properties of Azo Dyestuffs.

INSTITUTION OF MECHANICAL ENGINEERS (Informal Meeting), at 7.—Discussion on Pitfalls for Patentees.

SOCIETY OF CHEMICAL INDUSTRY (South Wales Section) (at Swansea Technical College), at 7.30.—E. A. Tyler: Fine Chemicals.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—E. F. Etchells: How to apply for a Job and how not to do it.

INSTITUTE OF METALS (Sheffield Section) (at Sheffield University), at 7.30.—J. A. Lee: The Evolution of the Furnace.

NORTH EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Middlesbrough Graduate Section) (at Cleveland Scientific and Technical Institution, Middlesbrough), at 7.30.—Debate: Industrial System, English, opened by K. Porter and J. Matheson, *versus* American, opened by T. W. Worth and H. McIvor.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Sir Arthur Keith: Concerning the Rate of Man's Evolution.

SATURDAY, MARCH 7.

ASSOCIATION OF TECHNICAL INSTITUTIONS (Annual Meeting) (at Institution of Mechanical Engineers), at 11 A.M.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford, The Counting of the Atoms (II.).

IPSWICH AND DISTRICT NATURAL HISTORY SOCIETY (at Ipswich).—Dr. F. W. Crossley-Holland: Science and the Criminal.

PUBLIC LECTURES.

SATURDAY, FEBRUARY 28.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—W. J. Perry: The Ancient *Mariners of the Pacific*.

MONDAY, MARCH 2.

ST. THOMAS'S HOSPITAL MEDICAL SCHOOL, at 5.—Prof. B. P. Watson: Puerperal Sepsis (I.) (Succeeding Lectures on March 3, 4, 5.)

LEEDS UNIVERSITY, at 5.15.—R. E. Priestley: The Glacial Cycle as illustrated by Antarctica.

UNIVERSITY COLLEGE, at 5.30.—P. Fleming: The Story of Regent's Park and Regent Street.

TUESDAY, MARCH 3.

KING'S COLLEGE, at 3.30.—Rev. R. Hanson: *The Philosophy of Religion* (VI.) Is there an *a priori* Religious Judgment?

IMPERIAL COLLEGE—ROYAL SCHOOL OF MINES, at 5.30.—Prof. C. A. Edwards: Chemical Combination in Metallic Alloys and its Nature (I.). (Succeeding Lectures on March 4, 10, 11.)

UNIVERSITY COLLEGE, at 5.30.—W. J. Perry: The Spread of Culture.

LEEDS UNIVERSITY, at 8.—Prof. W. Garstang: The Terrestrial Zoology of Yorkshire.

WEDNESDAY, MARCH 4.

LONDON SCHOOL OF ECONOMICS AND POLITICAL SCIENCE, at 5.—F. Pick: The Principles of Design as applied to our Cities and Towns.

SCHOOL OF ORIENTAL STUDIES, at 5.15.—E. Richmond: Early Moslem Architecture. Fâtimid Architecture in Egypt.

KING'S COLLEGE, at 5.30.—Sir E. Denison Ross: Travel and Travellers of the Middle Ages (VIII.). Travellers' Tales and the Kingdoms of Prester John, A.D. 1150–1550.

UNIVERSITY COLLEGE, at 5.30.—C. R. Sanderson: The Library Resources of London.—Prof. T. B. Wood: The Nutrition of the Young Animal (I.). (Succeeding Lectures on March 11 and 18.)

THURSDAY, MARCH 5.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL, at 4.15.—Dr. C. Singer: The History of Influenza, Diphtheria, and Typhoid Fever. (Succeeding Lectures on March 12, 19.)

SATURDAY, MARCH 7.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Miss M. A. Murray: Modern Excavations in Egypt.

SATURDAY, MARCH 7, 1925.

Medical Research in Great Britain.[1]

THE Report of the Medical Research Council for the year 1923–24 to the Committee of the Privy Council for Medical Research consists for the most part of a condensed epitome of the results already achieved during the year by research workers wholly or in part financed by the Council The large number and great variety of the researches undertaken make it impossible to refer to them individually in this article. Mention will, therefore, be made of a few subjects only which, either from the completeness of the issue arrived at or from the interest of the results obtained at the present stage of the inquiry, force themselves upon the attention.

Results of far-reaching importance are being achieved by the committee appointed under the chairmanship of Prof. J. Barcroft to investigate the properties of hæmoglobin ; and a paper on the correlation between the spectra of various hæmoglobins and their relative affinities for oxygen and carbon monoxide has recently been published from Prof. Barcroft's laboratory in Cambridge. Using the Hartridge reversion spectroscope, it was found that a relationship existed between variations in the gas-binding affinities of different hæmoglobins and in the character of the α-bands. These variations appear to be conferred on the hæmoglobin by differences in the protein part of the molecule.

That light was a potent means of disturbing the equilibrium between hæmoglobin, carbon monoxide, and oxygen was confirmed by the investigators engaged in this research, and its action on other biological processes is being intensively studied by many workers at the present time. It has been found that the bactericidal power of blood is raised by exposing the skin of the subject to ultra-violet radiation, the exposure causing in some obscure manner a greater avidity of the leucocytes for the organisms with which they come in contact. This result may be related to the now well-known beneficial action of sunlight in tuberculous infection in man, an action which is being demonstrated with such success by Rollier at Leysin and by Gauvain in Great Britain

It is not alone in its power of increasing the resistance of individuals to microbic infection that light is being exploited in research schemes at the present time Rapid progress is being made in the elucidation of the relation between irradiation and dietetic deficiency. It had previously been shown that exposure of rats fed on a diet deficient in fat-soluble vitamins to ultra-violet radiation was capable of bringing about normal growth. This effect was found to persist if the containers in which the animals lived were irradiated, and the result was interpreted as pointing to some property

[1] Committee of the Privy Council for Medical Research. Report of the Medical Research Council for the year 1923-1924. Pp. 142. (London: H.M. Stationery Office, 1924.) 3s 6d. net.

conferred by the ultra-violet light on the air in the immediate environment. Independent experimentation, however, failed to confirm this; and quite recently the original observers of the phenomenon have come to the conclusion that the positive results obtained by them were due to the presence of sawdust in the glass containers during the period of irradiation. When a piece of deal board was substituted for the dust an intermediate rate of growth was found. No precautions were taken to prevent the animals consuming some of the sawdust or gnawing away pieces of the irradiated board; but experiments at present in progress suggest that actual ingestion of the irradiated material is not essential for its beneficial action.

This result, if confirmed, is clearly one of fundamental and far-reaching importance. In the experiments referred to, the values for calcification of the bones were found to follow those of growth very closely. Whatever the nature of the emanations from these materials after exposure to ultra-violet light may happen to be, it is clear that a whole new field for research is rapidly opening up. What substances are capable of "phosphorescing" in this manner? Is vitamin A, the origin of which we know to be absolutely dependent on sunlight, a substance in which the power of absorbing ultra-violet light and converting this energy into a form of emanation having a potent effect in controlling the vital processes of growth and calcification, and is it developed to an extreme degree?

The Standards Department of the National Institute for Medical Research has now practically completed the work involved in the preparation of a stable dry standard of insulin. The Toronto unit will be defined in terms of this standard, which should then serve "as a currency for its transmission to all countries."

Much work is in progress on the nature and location of the action of insulin, when injected into animals, in causing the well-recognised fall in the blood sugar concentration. It had previously been shown by two Canadian physiologists that the isolated mammalian heart perfused with Locke's solution caused a fall in the sugar content of the perfusate, and that this fall was accentuated by the addition of insulin. The destiny of this extra quantity of sugar which disappeared remained, however, obscure. The question has recently been reinvestigated at the National Institute for Medical Research. Determination of the quantity of sugar disappearing in a given time, and the amount of carbon dioxide produced by the heart during the same period, have shown that in the absence of insulin there is a yield of carbon dioxide greater than can be accounted for solely by the combustion of the glucose removed. In the presence of insulin, however, the reverse is the case.

It is certain, therefore, that under the latter conditions part of the sugar is not oxidised, and at the present time the form into which the sugar has been changed remains obscure. It has been possible, however, to exclude certain hypotheses, such as that of the transformation of some of the sugar into fat, from a study of the respiratory quotient of the decapitated and eviscerated animal under constant infusion of dextrose. In such a preparation, insulin causes the characteristic fall in blood sugar, even when the muscles are inactivated by curare, without any change in the respiratory quotient which remains throughout at unity. Immediate transformation of the sugar into fat, or into lactic acid, seems therefore to be definitely excluded. Furthermore, investigations at Cambridge have shown that the heat production of isolated frog's muscle is unaffected by the presence in the surrounding fluid of relatively large concentrations of insulin. Recent work, too, on the sugar consumption of the heart-lung preparation has failed to show an increase in the rate of disappearance of this substance from the circulating blood on the addition of insulin. Insulin apparently is essential at some stage on the anabolic ladder of glycogen formation, though it will be clear from the foregoing account that we are still ignorant of the intimate nature of its action.

Studies of the excess metabolism of muscular exercise in man over and above the resting level have shown that this, provided the exercise is short-lived, has a respiratory quotient of unity. Experimental evidence all tends towards the conclusion that muscle is capable of metabolising directly carbohydrate alone.

It will be apparent from the few foregoing examples of work which is being pursued in the physiological and biochemical laboratories of Great Britain, that these two sciences are extremely virile and rich in productive effort. Turning to experimental medicine and clinical research, we find that here again much progress is recorded and "the Council are of opinion that during the past five years these University clinics have wholly justified their foundation by their success." Where the material for research is human, it is unavoidable that advance should be slower than in the sciences contributing to medicine. Furthermore, we must remember that the staffs of the medical and surgical units of the London hospitals are not in a position officially to exercise their option as to the type of case admitted to their wards any more than their colleagues on the remaining hospital "firms."

For teaching purposes this is no doubt an advantage, but it must inevitably break any attempt at co-ordinated research into the mechanism of the disturbances which culminate in disease. The first effective trial unit made by the Medical Research Committee, namely, the

Cardiac Department of University College Hospital Medical School, has more than justified its existence. This unit is unique in that it is engaged in an intensive study of the physiology, pathology, and nosology of one system only; a fact which is probably not unrelated to the richness of its scientific produce. The conception of "capillary pulsation" as a sign primarily of high pulse pressure, and in consequence a common accompaniment of aortic insufficiency, has been shown to be erroneous, the main causative factor of the phenomenon being a "widening of the arterioles of the skin or mucous membrane in which it occurs." The capillaries of the human skin have been shown to be capable of exerting relatively high pressures (from 50 to 100 mm. of mercury) when they are stimulated to contract by light stroking of the skin. Injury to the skin, on the other hand, leads to a train of vascular changes—dilatation and increased permeability of the minute vessels—which is conditioned by the liberation from the injured cells of a substance akin to histamine. To quote from an original paper,

"from the simple reactions of a healthy skin to the relatively mild stimuli such as are experienced daily by almost all; through the more serious, though trivial, local injuries, the bruise, the blister and the small scald, which find their simple household remedies; to the most grave mechanical injuries and extensive burns which in their late manifestations endanger life, we pass by transition It begins to be apparent why this transition is throughout a transition of quantity and not of quality; for underlying the whole series of reactions there is seemingly one chief determining cause, the unvarying reply of the affected cell to injury; this response of the cell, protective as it is to the cell itself, when united with that of neighbours, produces a massive action, threatening or terminating the life of the organism as a whole; an example which is not the sole example of conflict between the cell and the community of which it is a member."

In the introductory review by the Council of its second quinquennium, attention is directed to the unsatisfactory position and progress of pathology and bacteriology. It is pointed out that in Great Britain this is in part due to the "accidents of historical circumstances," but that "in all countries bacteriology is halting for more intimate knowledge of the infective organisms and of their biochemistry, while pathology only shows promise of advance in so far as it proceeds as a study of the reactions of the body to disturbance, as a part indeed of physiology, and in so far as it can express its phenomena in terms of biochemistry."

The munificent benefactions which these two sciences have recently received at the Universities of Oxford and Cambridge through the generosity of the Dunn Trustees, the Rockefeller Foundation, and Mr. Ernest Gates, coupled with their full recognition by the universities as being sciences laudable of pursuit, will, however, doubtless raise their position rapidly and effectively to the level and productive capability of those sciences which are less directly concerned with the alleviation of human suffering.

It is impossible to read this Report of the Council without being impressed with the wide range of its activities and the wisdom it displays in allocating the funds entrusted to it by Parliament for the furtherance of medical research. E. B. V.

MODERN science has changed the size and shape of the earth. Time is the measure of its distances and routes the framework of its shape. London is nearer to New York than to Kashgar, and the Pacific Ocean, once the limits of the Orient and Occident, is now becoming the strategic and economic centre of a new world based upon the universal ocean. The latest development is a bi-weekly service of motor cars across the French Sahara. The adjustment of human activities to physiographic conditions has been in progress from before the dawn of history, and human institutions have shown that they are no more permanent than the "everlasting" hills.

The author of "Geography and World Power" defines history in its widest sense on its material side as the story of man's increasing ability to control energy. In a most suggestive book he gives a series of excellent studies, showing how empires and states have developed conformable to certain major phenomena of a physical order, and how a change in geographic values has effected changes in the relative importance of nations. Some, no doubt, will quarrel with the word "control," and especially so when it is urged that

"Men may advance or fall behind because the geographical conditions affecting their bodies react on their minds"; and again: "In the long run the geographical conditions are more powerful than the genius of individuals, more powerful even than racial characters, unless these racial characters are due to geographical controls."

The genius of mankind shows itself in its adaptability to new physical environments and an increasing ability to harness or to modify certain natural phenomena. The modern farmer in Saskatchewan shows an entirely different adjustment to the natural conditions from that of the Indians who preceded him, though no doubt the influence of the prairies is as marked on the social and economic life of the present inhabitants as on the culture of the Plains Indians, their former occupants But time is on the side of man. The cutting of the Suez and Panama canals, the irrigation works of California and S E. Australia, are of the same order as the works of Nature which are said to be "controls"; and these are but an earnest of still greater scientific achievements. The hot deserts may not only be made to blossom as the rose, but these areas of excessive insolation may also become the power stations of a new age when man has used up his capital energy of oil and coal. Nevertheless, the main thesis holds true that world power, at present, is closely related to the ability of man to utilise the physiographic conditions of his region. A knowledge of the manner in which man to-day is adjusting himself to the modern complex conditions of world occupancy ranks high in the essential sciences *Wissen ist Macht—Geographisches Wissen ist Weltmacht!*

The volume on North America furnishes not only innumerable illustrations of these principles, but also shows how these principles operate in the modern world. The first part traces the influence of physiographic conditions on the progress and development of settlement in America by emigrants from Europe. The second indicates the conditions which have arisen in North America from the application of modern science to the utilisation of coal, oil, and iron, and to the cultivation of wheat and cotton, both groups being extractive industries which are essentially localised The third part reviews these historical and economic considerations from a geographical view-point, and discusses the present-day adjustment of life and labour which makes the geographic region a more powerful entity than the individual state. Both the localisation of industries, as the iron and steel on the Pennsylvania coalfields, and the cultivation, and in these days the manufacture, of cotton on the warm fertile lands of the Atlantic and Gulf plains, give rise to regional interests of a very definite character. Dr. Bowman states in his book, "The New World," in a section devoted to America: "To a much greater degree than an outsider might suppose, and in spite of all the patriotic assurances to the contrary, there is a deep underlying question in the minds of thoughtful men in the United States as to the continued unity of the nation." He reiterates the words of Prof. Turner that to-day the United States is a federation of sections rather than of states, and that even a map of political votes roughly outlines the geographic provinces of the country.

Regional development is not, however, antagonistic to national unity. Indeed, it often furnishes the driving force of political or economic expansion. Most of the world-development problems of our time are questions of political or economic frontiers largely developed by expansive forces generated regionally within the political boundaries. Regional consciousness is expressed within the nation, national consciousness within the world itself Though there may be, and often is, a physical and historical background, the delimitation of political divisions is often of an arbitrary character. Europe bears on its new political map the evidences of both the constructive and destructive forces let loose by the War. The pre-War tendency towards consolidation into great and powerful states has been followed by disintegration into innumerable new states, as Poland, Czechoslovakia, and Yugoslavia, the uprising of which can be explained, if not also justified, by considerations of a physical, racial, or economic character. As a statement of the new political position within the "peninsula" of Europe, together with a certain amount of useful data about each state, the volume on Europe serves as an excellent reference book. It is what it claims to be, a "compendium" rather than a geographical treatise. Such is the organisation of a modern state that, complex as may be the adjustment of life and labour to the physical conditions of the area, it forms a body politic capable of determining policies affecting not only its internal but also its external affairs. Political lines will sever what Nature has joined, often dividing physiographic or economic regions into two or more geographic entities, as between the United States and Canada or between France and Belgium. On the other hand, political boundaries may bring a number of regional entities into a single political expression, as in the United States or France.

Though the political divisions may be somewhat arbitrary, the regional divisions within the state tend to be based on considerations of an economic character, which in turn may rest largely on physiographic foundations. The region has a distinctive life of its own, and the regional consciousness is more than the whirr of

its machinery or the rattle of its trains and lorries. It springs from an adjustment of life and labour to the area, and it lives, not so much because of the factors which brought one or more of its industries into being, but because of its functions to-day. A British company desirous of erecting additional cotton mills would place them in South Lancashire, not because of those factors which first attracted the industry, but because to-day the region possesses the machinery for dealing with the cotton trade; there are located the necessary subsidiary trades, and there is the great reservoir of labour skilled in the processes of cotton manufacture.

South Lancashire to-day lives, no doubt, on cotton, but fate has not decreed that it must die if cotton be withheld, providing the withdrawal of the raw material is sufficiently gradual to allow a readjustment to new activities. Man's salvation lies in his adaptability. London, like some urban Vicar of Bray, has accommodated itself to and grown with the changing conditions of the British Isles, thereby retaining the premier position in trade and commerce. If geographical science can so study what one may call the anatomy and functions of the region, diagnosing incipient diseases and prescribing cures, it will render invaluable aid not only to the body politic of which the region is a limb, but also to the millions of people whose lives are more or less anchored to the area. Must New England necessarily perish because the Southern States have now entered into competition with it?

"North America" and "The New World" furnish innumerable illustrations of world development, both in the purely geographic region and in the political region, which in these days assumes a geographic form. The former to-day conforms largely to an economic or physiographic foundation, because a region, like an individual, must in general live by work. One example from "North America" must serve. The broad indentation of the east American coast between Capes Cod and Hatteras appears on a relatively small scale map as an unnamed bay sweeping inward to the foothills of the Appalachians, broken in outline by three large inlets, Long Island Sound with the Narrows, and Delaware and Chesapeake Bays. These give access to river valleys which lead across the mountain barrier to the rapidly developing manufacturing and agricultural regions beyond. Population in the narrow belt of broken lowland has gathered round the three port nodals of New York, Philadelphia, and Baltimore. They and the surrounding districts form a region of considerable importance, though it is not easy to state exactly the causes of its growth. The most powerful may well be the very size and adjustment of the present population, compelling the consideration of the factors of its origin to be made in the light of modern demands and opportunities. What is said of New York, London, Berlin, and Paris may be applied to all great ports and their hinterlands. "Every individual quota to provincial population, whether industrial or agricultural, has its counterpart in metropolitan expansion." Every development in the hinterland has a corresponding development in the port. Yet Salem in New England and Chester in old England failed to keep the developing traffic of their hinterlands, and succumbed to Boston and Liverpool respectively. Great and prosperous cities have declined, and often the germ of decay has been secreted in the heyday of prosperity. When geographical science can not only observe accurately the full foundations of regional prosperity, but can also form an estimate of the vitality and capabilities of the region, it will have made a contribution of prime importance to mankind.

The political region or state presents a geographical study of a somewhat different order. The very rigidity of the frontier is incompatible with the economic development within and the expression of the national consciousness without. "The New World" is an exhaustive and masterly study of problems in political geography. They are problems of the frontier, either political, economic, or social. Dr. Bowman asks: "Will the changes in the political and economic geography of the world spell peace or war, strength or weakness, in the years immediately before us?" He then makes the comment that there are about 10,000 miles of boundary round the states of central Europe alone, of which more than 3000 represent newly located boundaries. "Every additional mile of new boundary, each new location, has increased for a time the sources of possible trouble." Indeed, it may not be too much to say that the conflicts of expanding frontiers have probably been far more determinant of historical development than the physical conditions over which these frontiers have passed.

The principal cause of regional growth, accompanied by economic or political expansion, lies in the increasing ability of man to develop and utilise the world's resources. This ability is most evident in the large, well-organised states, and creates not only the desire but also the power to push outwards into the world market. Economic or commercial geography throws considerable light on the character and direction of these movements, affecting not only the Great Powers of the world, but also the many states of Europe and Latin America. The "Elementary Commercial Geography" is a useful introduction to this aspect of geographical study.

The effect of the frontier in American history has long been recognised. But the expanding frontier did not rest on the shores of the Pacific States. In

Alaska and the Aleutians, Central America and the Caribbean Sea, in Hawaii, the Philippines, and other Pacific Ocean islands, the United States has extended its political possessions, and this has been accompanied by a still greater expansion of its commerce and prestige in South America and the Far East Britain, France, Japan, and other nations differ from the United States not in kind, but merely in degree The consequence is that world development is being accompanied by conflicting interests over wider areas than the mere frontier zones of individual states Countries nominally independent, as China, and states under the administration of European powers, as those of Africa, are feeling the effects of world development Moreover, the change in the regional life is not measured merely by the change in economic values There is a profound change in the people themselves The old order changes, giving place to new. A new orientation and a new outlook are rapidly being developed The population, under the external stimulus from Europe or America, is adjusting its life and labour anew to the physiographic conditions and possibilities of the region The African, the Egyptian, the Chinese, and a thousand other "questions" arising with world development have a regional basis, and demand the urgent and careful investigation of the new science of geography

Some Sponges of the Southern Seas.

British Museum (Natural History), British Antarctic ("Terra Nova") Expedition, 1910. Natural History Report. Zoology Vol. 6, No. 3. *Porifera.* Part 1: Non-Antarctic Sponges. By Prof. Arthur Dendy. Pp. 269 + 392 + 15 plates. (London: British Museum (Natural History), 1924) 17*s* 6*d*.

PROF DENDY has produced a very beautiful and elaborate memoir on the sponges collected by the *Terra Nova* expedition in the southern seas. It is possible that such a highly technical piece of work may appeal only to a few readers at the present moment, but it can nevertheless be recognised as a permanent and important contribution to zoological science.

The modern developments of biology in the directions of embryology, the problems of heredity, experimental zoology, and comparative physiology have proved to be especially attractive to the younger generation of biologists, and no one can deny the value and importance of the scientific results of their work in the new fields of research that are being opened It must be remembered, however, that the accurate and detailed description of new and old species, especially when it is accompanied by sound judgment in systematics, and careful consideration of the possibilities of natural variation and powers of adaptation to environment, is an important and indeed fundamental branch of the science of zoology. There is indeed a pressing need, at the present time, for more work of this description if we are to keep pace with the receipt of specimens that collectors are sending to Great Britain from all parts of the sea and land. To workers in this line, Prof. Dendy's account of the sponges may well serve as a model of what such monographs should be, and it is a great satisfaction to realise that some of our ablest zoologists are still willing to devote their time and expert knowledge to the production of systematic treatises of a high standard of merit.

All the sponges, except three, described in this memoir were obtained by five hauls of the dredge in water extending from the shallows to a depth of 100 fathoms off the north of New Zealand The cruise revealed a very remarkable and, at the same time, a very rich fauna of sponges in these seas, such as has not yet been equalled in any region of the world In these five hauls no less than 90 species were discovered, and of these 62 appear to be new to science. If it were to occur to any one on reading this statement in the introduction that in such a restricted area some of these species must be variations or mutations of relatively a few species, such a criticism would be dispelled by the careful description of the form and particularly of the spicules of the sponges the author describes.

The problems associated with the occurrence of such a remarkable assembly of organisms of the same group competing fiercely with one another for the advantages of the situation are not ready for solution, but the record of this wonderful sponge fauna is of importance in the science of the distribution of animals, and should not be lost sight of or forgotten because it is buried in a systematic treatise.

It is difficult to select from the many detailed descriptions of species the points of special interest for the general zoologist. The extraordinary range in form and structure of sponge spicules and the numerous technical terms that have been invented for them may be bewildering to those who are not well acquainted with the literature of the group, but there seems to be no doubt that in the Porifera the spicules are more constant in character for each species, and therefore more valuable for systematic purposes, than they are in the Alcyonaria. Accurate description and careful illustration of the spicules is an essential feature of a good monograph on sponges.

The discovery of two fine new species of the interesting group of hexactinellid sponges is a welcome and noteworthy point in this work.

The monograph is well illustrated by fifteen quarto plates, and we have to thank Prof. Dendy also for a good index.

The Rat Menace.

Rats and How to Destroy Them; dealing with Rats in a House, Shop, Warehouse, Outbuilding, Yard, Stable, Cow-house, Fowl-house, Pig-sty, Garden, Greenhouse, or Vinery; by a River, Stream, or Ornamental Water; on a Ship, Shooting Estate, or Farm; and in Sewers. By Mark Hovell. Pp. xlii+465. (London: J. Bale, Sons and Danielsson, Ltd., 1924.) 10*s.* 6*d.* net.

IT has been estimated that the damage caused by rats to the food supply and buildings in Great Britain alone represents a loss of something approaching 50 million pounds a year. In addition to this, the rat is a serious menace to society as a carrier of disease; the occurrence of infectious jaundice in epidemic form on the western front during the War and more recently in Scotland, where a mortality of 40 per cent of cases occurred, has directed attention to a new danger near home, for which the rat is responsible. It is common knowledge that rats are prolific, but few people realise the rapidity with which their numbers increase. The litter in an adult rat varies from 8 to 16. Rats breed throughout the year, the period of gestation is only 21 days, and impregnation may again take place within a few hours of the birth of a litter.

A very moderate estimate of the number of descendants of one pair of rats born during one year is well over a thousand, and these in the course of three years will have increased to a quarter of a million; these calculations are based on litters of 10, and only 6 litters in the course of a year are allowed for. A single pair of rats will eat more than 80 quartern loaves or their equivalent in a year, and their descendants in the same year will eat more than 46,000 loaves or their equivalent in wheat or flour.

After reading the introductory chapter of Dr. Hovell's book in which these and many other interesting facts are lucidly presented, one cannot remain apathetic to this ever-increasing menace to humanity. The remainder of his book deals chiefly with all the known methods of preventing the spread of rats and destroying them in every conceivable situation. Traps of every description are described, with many illustrations, and the relative values of all the better known forms of rat poison are dealt with. A very interesting chapter is devoted to the history of bubonic plague, and the way in which it is carried by the various rat fleas. It is interesting to note that, even in Old Testament times, rats were in some way held responsible for the spread of plague, continual reference being made to "golden mice" which were made "as an offering for the Plague."

There is a short section on rat cancer and the life history of the nematode (*Spiroptera neoplastica*) which causes this disease in the stomach of the rat and passes its larval stages in the muscles of a species of cockroach. In this and in his remarks as to the possible relation of human cancer to cockroaches, the author is perhaps a little misleading, as he does not state that the cockroach in question is the New World cockroach *Periplaneta americana*, and not *Blatta orientalis*, which is the one common in Europe.

There is an appendix dealing with a scheme for the organised destruction of rats throughout the country, but though this would seem to be a highly desirable step, it would require special legislation to enforce.

The book is one which will direct public attention to a very real menace and at the same time be of the greatest assistance to those who are brought into direct conflict with that menace.

Our Bookshelf.

Masters of Science and Invention. By Floyd L. Darrow. Pp. v+350+24 plates. (London: Chapman and Hall, Ltd., n.d.) 10*s.* 6*d.* net.

IN recent years progressive science teachers have been pondering the problem of "humanising" scientific instruction, of introducing the breath of life into the "valley of dry bones" of experiment, observation, and inference, and thus in a measure treading on the ground hitherto monopolised by the humanists. The work under notice represents an attempt in this direction. The author has set himself the difficult task of giving, in simple biographical form, an account of the development of scientific achievement, and he states that "no knowledge of the laws of science and their manifold applications is even approximately complete without acquaintance with the outstanding figures who have made possible the age in which we live." In the twenty-eight chapters, each of which is more or less complete in itself, we are given an excellent bird's-eye view of the march of discovery and invention, which will especially appeal to the young—in years or knowledge.

Although we may question if biography is essential to the understanding of the content and method of science, there can be no doubt that its inclusion is a most valuable stimulus, particularly to that large majority which prefers the study of man to the study of Nature. This book is a very useful addition to popular scientific literature; the arrangement is good, the style is clear and vivid (but why, oh why, does the author never use a colon or a semicolon?), the selection of "masters"—an invidious task—is good, and the statements are generally accurate. Two errors in the chapter devoted to briefer biographies should be corrected: Sir Ernest Rutherford is no longer professor of physics at Montreal, and the late Sir William Crookes was never a professor either in the Royal College of Science, Oxford, or elsewhere.

An analysis of the nationalities of the men who are noted at length in this volume may be of interest. Of the men of science, about one-third are British, one-fifth French, one-sixth German, one-fifteenth each

American (U.S.A.), Swedish, and Swiss; whilst ninety per cent. of the inventors are either American or British. If these figures may be taken as a rough index of the distribution of scientific and inventive genius, it would appear that although science has no fatherland (as Pasteur said), invention can make out a good claim for the English-speaking world.

Complex Salts. By Dr. William Thomas. (Manuals of Pure and Applied Chemistry.) Pp. xi+122 (London, Glasgow and Bombay. Blackie and Son, Ltd., 1924.) 10*s*. net.

DR THOMAS'S book on "Complex Salts" is a small volume of about 120 pages, intended more especially for students reading for final and honours degrees. It differs from a recent book by Schwarz on "The Chemistry of the Inorganic Complex Compounds" (see NATURE, October 27, 1923, p. 617) in that it deals in a much more general manner with the problems of molecular asymmetry, optical activity, methods of resolution and rotatory dispersion of optically-active complex salts. On these subjects Dr Thomas has himself done important original work.

A novel and extremely valuable feature of the text is a chapter on the "Preparation and Resolution of Inorganic Complex Salts," including two examples of resolution, one involving the use of an active acid, and the other the use of an active base. This chapter should be of great value in enabling an honours student, or a young research worker, to secure experience in the manipulation of this important group of compounds. The book is presented in an attractive form, but the price appears to the reviewer to be rather high in view of the small size of the volume, although the price per page is appreciably less than that charged for the English translation of Schwarz's book.

The equilibrium-diagram which represents the case in which a racemate is formed when the temperature is raised, instead of (as in the case of sodium ammonium tartrate) when the temperature is lowered, appears to have been omitted, since Fig. 3, p. 60, represents the unsymmetrical diagram for a double salt which decomposes above a transition-point. It is not immediately obvious from the text what has gone wrong, and a student who encountered this error without knowing the correct form of the diagram might be puzzled for a long time before finding the correct interpretation.

The High Grass Trail: being the Difficulties and Diversions of Two; Trekking, and Shooting for Sustenance in dense Bush across British Central Africa. By Frank Savile. Pp. 255+10 plates. (London: H. F. and G. Witherby, 1924.) 15*s*. net.

THIS is a day-to-day account, written in an easy and pleasant style, of a shooting trip, undertaken in the high grass season, to Nyasaland and Northern Rhodesia. As no map has been provided, and most of the places mentioned are not marked on the ordinary map one has at hand, it is not easy to follow, except in a general way, where the author really did go.

This part of the world seems to be a veritable sportsman's paradise, both as regards small and big game. There was something to shoot almost every day. The natives are extremely friendly and willing to assist in all operations of shikar. Their intense desire for meat makes them very ready helpers where big game is concerned. In a country where supplies are so scarce it is necessary to ply the gun in order to keep the larder replenished, and provide food for an army of carriers. Some game, however, is not exactly up to the white man's standard. Of zebra meat the author remarks: "It is dark, unwholesome red, greasy and revolting. I have tried the brains and tongue, which are passable, but so far, to Allah be praise, have never had to set my cheap German teeth the task of masticating its steaks or cutlets," but "the ordinary nig. loves it."

None of the problems of the country are dealt with. It is purely a book for the sportsman, and any one contemplating a visit to British Central Africa for shikar purposes should certainly read it. It will give him a good idea of what to expect as well as a considerable amount of entertainment. H. L. C.

Chambers's Encyclopædia: a Dictionary of Universal Knowledge. New edition. Edited by Dr. David Patrick and William Geddie. Vol. 4: Dioptrics to Freistadtl. Pp. iv+856. Vol. 5: Fréjus to Humboldtia. Pp. iv+840. (London and Edinburgh: W. and R. Chambers, Ltd., Philadelphia: J. B. Lippincott Co., 1924.) 20*s*. net each vol.

THE most recent volumes which have appeared of this handy encyclopædia carry the alphabet nearly to the end of the letter H. They are well supplied with finely produced coloured maps, of which the historical maps of Europe and the physical and geological maps of Great Britain are particularly useful. Most of the articles of the last edition have undergone revision, in some cases by the original writers, and references to recent events have been added. Other articles have been re-written. Many of them are models of summarised knowledge, and several on the more important subjects run to considerable length. Thus "electricity" covers twenty-six pages, with another eight pages on cognate subjects. "Eye" runs to twelve and "fishes" to seven pages. Cross-references enhance the value of the work, but do not occur so frequently as to impede quick reference.

Elementary Experimental Statics for Schools. Written by A. P. McMullen. Revised for the Press, with some additional Matter and a Preface, by E. W. E. Kempson. Pp. vii+315. (Cambridge: At the University Press, 1924.) 8*s*. 6*d*.

IF the object in teaching a subject such as statics to schoolboys is not so much to give them anything in the nature of a logical training as to render them appreciative of the fundamental principles and convinced of their truth, no better system can be adopted, we believe, than the experimental method. Especially is this the case in the present age, when boys display a lively interest and knowledge of machines, and appear to have relatively little difficulty in grasping the idea of mechanical work. It is for this reason that the authors of the present book have developed their subject in the order work, moments, triangle of forces, dealing in their appropriate places with friction, centres of gravity, equilibrium and stability. The result is that they have produced a book which must be of real value to all teachers of the subject. The illustrations are copious and instructive.

Letters to the Editor.

Local Reflection of Wireless Waves from the Upper Atmosphere.

In some recent experiments carried out for the Radio Research Board of the Department of Scientific and Industrial Research, measurements have been made of the diurnal variation of the signals received at Cambridge from the stations of the British Broadcasting Company. During the day-time these signals have been found to be fairly constant, but night-time variations of intensity have been measured at distances from the transmitter so short as 50 miles. For example, the signals from London at Cambridge are found to be constant during the day; but, at about sunset, variations, which are often of a periodic character, begin, and continue through the dark hours. In this case the mean night value is very little different from the day value. For more distant stations (for example, Bournemouth) the phenomena are different. During the day the signal is weak and constant, but after sunset the intensity increases and, though variable, the signal maxima may be several times the day value. In this case the variations in signal intensity are larger, less rapid, and less markedly periodic than in the case of the London signals.

These effects may be explained in a general way if an atmospheric reflecting layer is postulated which is comparatively ineffective for the waves of this frequency during the day-time but bends them down very markedly at night. According to this view two rays arrive at the receiver at night, one nearly along the ground, which may be called the direct ray, and the other returned from the atmosphere, and called the indirect ray. In the case of the London signals the direct ray is considered as being strong and constant compared with the indirect ray, and the night-time variation is considered as being due to interference between the direct and the weak indirect ray. For the longer distance transmission, the stronger night-time signal is to be attributed to the indirect ray.

If the reflecting stratum is imagined to be at a height greater than say 50 kilometres, the above interpretation indicates bending back at relatively small angles of incidence (for example, if London is considered, and the height is assumed to be 100 kilometres, this angle of incidence is about 22°). Such high grazing angle reflection from the Heaviside layer has not usually been considered possible, and we have therefore attempted to examine the phenomena in a more direct manner. The method adopted has been to vary the frequency of the transmitter *continuously* through a small range and attempt to detect the interference phenomena so produced between the two rays. From our measurements it was estimated that at a distance of about 160 kilometres from the transmitter, the effects of the direct ray and the indirect ray at night would be approximately equal.

The British Broadcasting Company, on being approached, very kindly consented to collaborate in the experiments and to use the Bournemouth station as the transmitter. Oxford, being about 140 kilometres from Bournemouth, was chosen as the receiving site, and excellent facilities for the installation of the receiving station were provided for us in the Oxford Electrical Laboratory by Prof. J. S. Townsend and Mr. E. W. B. Gill. Capt. A. G. D. West, of the B.B.C., who was in charge of the Bournemouth end of the experiment, arranged the transmitter so that a known frequency change could be produced uniformly during a given time (for example, 10 to 30 seconds) while the aerial current remained practically constant. The received signal intensity at Oxford was determined with a receiver specially designed to give approximately uniform sensitivity over this band of frequencies. The resulting signal currents were measured by moving coil and small Einthoven galvanometers. Mr. F. G. G. Davey gave us most valuable assistance at the receiving station. Land-line communication was also maintained between the two stations during the period of the experiments for control purposes.

Two sets of experiments were carried out on December 11, 1924, and on February 17, 1925, and in both cases quite definite examples of successions of interference bands were observed as the wave-length was changed, the intensity varying from a maximum value almost to zero as was arranged for by choice of distance. If we assume the simplest interpretation of these interference phenomena and regard them as analogous to those of a Lloyd's mirror fringe system, the effects may be viewed as follows. For a direct ray path of length a, a higher ray path of length a' and a given wave-length λ, the higher ray arrives N wave-lengths behindhand as compared with the lower ray where $N = (a' - a)/\lambda$. If N is an integer the waves steadily reinforce unless a' is changing, while if N is halfway between two integers they are steadily opposite in phase. If the wave-length is gradually increased to λ' at the sending station, alternations of intensity may be expected, the number being $(a' - a)/\lambda - (a' - a)/\lambda'$. The experimental observations according to this simple interpretation indicate a path difference $(a' - a)$ of the order of 80 kilometres, which is consistent with a reflecting layer at a height of about 85 kilometres. Evidence was, however, obtained that the results may be somewhat complicated by the elliptical polarisation of the indirect ray, in which case the above estimate of the height may have to be revised. Further experiments on this point are in progress. But the interference phenomena between two rays depending on the existence of a deflecting layer seem definitely established.

It has been usual to attribute the difference between day and night strengths of wireless signals to a difference in the sharpness of the boundary of the effective atmospheric layer, the lower boundary being assumed sharper by night than by day. We think, however, that the transition cannot be sharp compared with the wave-length, particularly for the short waves we have used, and therefore the term "reflection," used for convenience above, must be taken as meaning "ionic deflection."

We imagine, therefore, that at night the layer is sufficiently high and intense to permit of ionic deviation taking place, the ray being turned through large angles without undue absorption. During the day the ionisation due to solar agencies throws the ray down at lower levels (for example, 40-50 kilometres), and here, although ionic refraction can take place, the collisional "friction" causes heavy absorption at these short wave-lengths and high grazing angles. The difference in the action of the atmospheric ionisation between day and night is therefore to be taken as due to the differences in height (and therefore density) of the effective layer, and not as due to the difference in the sharpness of the boundary of the layer, as has been usually assumed.

These and other experiments suggest the inference that, at distances greater than about 100 miles from a wireless transmitter of these wave-lengths (for

example, 300-400 metres), night-time reception is dependent almost entirely on the upper indirect ray; and evidence is not lacking that, due to the more effective reflection by the ionised layer at smaller grazing angles, the signal strength maximum may in some cases increase with increase of distance from the transmitter

The Propagation of Radio Waves over the Earth.

AMONG the facts to be explained in a satisfactory theory of the propagation of radio waves over the earth's surface are the curvature of the rays in transmission between stations far apart, the absorption during transmission, the peculiar phenomenon of fading, in which the magnitude of the received wave fluctuates more or less rapidly, the differences in transmission in different directions over the earth, and the extraordinary differences in the transmission of long and short waves.

This letter is to outline a new theory of transmission which accounts quantitatively for many previously unexplained facts of radio transmission. A detailed treatment of important cases will appear shortly.

The atmosphere to a considerable height above the earth contains ions which react upon electromagnetic waves and, as shown by Larmor (*Phil. Mag.*, Dec. 1924), may account for the bending of long waves around the earth. His explanation, however, does not show the large and characteristic differences between short and long wave transmission, which become especially marked in passing through the region between 100 and 200 metres. Other theories, also, have the defect of predicting entirely incorrect results for short wave-lengths.

The theory now developed takes into account both the earth's magnetic field and the distribution of ionised particles in the atmosphere. It is found that this field, together with the electrons, produces marked selective effects at wave-lengths between 100 and 200 metres, and that these effects are different for different directions of transmission and for different planes of polarisation of the wave. A summary of the effects follows.

For the case in which the electric force of the wave is parallel to the earth's magnetic field, the only effect is due to a variation in ionic density above the earth. This case is realised practically only over very limited areas of the earth's surface.

For transmission in any other direction or for any other direction of the electric field, four effects are in general produced, namely, the plane of polarisation of the wave is rotated by an amount depending upon the density of free electrons, the magnetic field, and the frequency. This effect reverses at the critical frequency, which, for a field of 0·5 gauss, is 1400 kilocycles (214 metres). The second effect is that of double refraction in the medium, producing two waves of different velocities and polarisations. The third effect is a bending of the rays due to a variation in ionic concentration, as in Larmor's case, but, due to the magnetic field, this bending also, in most cases, reverses at the critical frequency, so that if long waves bend down in a certain region, short waves will be deflected upwards in the same region. The fourth effect is a bending of the rays due to variations in the magnetic field strength, and this effect also reverses at the critical frequency.

The general solution of this problem cannot be given in this note, but some interesting special cases will be described.

For transmission from a vertical antenna along a magnetic meridian the electric vector tends to be rotated, and, when this rotation becomes equal to 90°, the usual methods of reception produce no signals; hence we should expect, in general, better reception of east-west than of north-south signals at certain points. Also, since the plane polarised ray can be resolved into two circularly polarised rays travelling with different velocities, under certain conditions both components may not be able to travel over the same path between two points.

The rotation of the plane of polarisation for transmission along the magnetic field is rather large, for example, the electric vector in a wave 2 km. long will turn from vertical to horizontal in about 80 wave-lengths if there are present only 10 free electrons per cubic centimetre in a layer for which the mean free path is sufficiently long for free motion. A wave 100 metres long will rotate through the same angle, but in the opposite direction, in about 5000 wave-lengths or 500 km. For larger ionic densities, appropriate to high levels, the waves may be rotated very rapidly, which is one of the causes of variable transmission along a magnetic meridian.

For transmission at right angles to the magnetic field, we find double refractions with the ordinary ray unaffected by the magnetic field and the other selectively affected.

In all these cases, the variation in the number of ions and in the magnetic field at different heights above the earth produces deflexions of the rays which may be calculated.

The introduction of a resistance term into the equations of motion of the electron leads to an attenuation factor in the equations of wave-motion. Thus, for transmission parallel to the magnetic field, the exponential term involves the reciprocal of the square of the frequency for frequencies sufficiently large compared to the critical value. This means, therefore, that attenuation due to this cause falls off rapidly as the frequency is increased. At the other extreme the same expression is found to apply, except that in place of the transmitted frequency, the critical value is substituted. Hence in this range attenuation due to this cause is constant. There are, of course, other causes of attenuation—for example, the conductivity of the earth.

When the frequency is near the critical value, large anomalous effects occur. For example, the wave may be required to travel over a widely different path by a slight change in either the magnetic field or the ion density. The signal may arrive at the receiver from several directions simultaneously or successively, producing fading or apparent change of direction. The absorption may become extremely high for certain rays.

The detailed theory, with its predictions, will be published soon.

Molecular Symmetry in Crystal Structure.

IT has been pointed out by Clark[1] that there is a great similarity between the structures of the four alkali polyhalides KI_3, CsI_3, $CsIBr_2$, and $CsICl_2$. They have the same arrangement of atoms in unit parallelepipeda, if the unit cells are chosen so as to contain one molecule. The arrangement is with the metal atoms at the corners of the cell and the halogen atoms inside the cell and in a line on the body diagonal.

[1] A. L. Clark, Pro. Nat. Acad. Sci., 9, 4, 1923, p. 112.

The same arrangement is taken up by the complex radicles in the hexammoniates of the nickel halides and the hexahydrate of zinc bromate. This body-centred grouping is a deformation of the arrangement in CsCl.[2]

A study of the chlorates, bromates, and iodates of sodium and potassium shows that similar relations exist between these salts. Some are closely related to cæsium chloride in structure, which we shall call the CsCl set, and the rest to sodium chloride, referred to below as the NaCl set. The distinction between the more complex salts and the simple halides is that in the former the chemical molecule can be identified, in the latter it cannot.

Sodium chlorate and sodium bromate have been studied by several workers.[3] They belong to the NaCl set, with four molecules per unit cell, the edge of the half-molecule parallelepipedon being 3·29 angstroms in the chlorate and 3·35 angstroms in the bromate.

The three potassium salts have been examined by the writer using the ionisation spectrometer, and the following results were obtained.

Potassium chlorate, which is monoclinic, belongs to the NaCl set. The half-molecule parallelepipedon has edges 3·56, 3·69, 3·69 angstroms. Potassium bromate is ditrigonal pyramidal (pseudocubic). Measurements on the spectrometer show it belongs to the CsCl set, the edge of the one molecule pseudocube being 4·46 angstroms. Potassium iodate is monoclinic (pseudocubic). The spectrometer method, and a photograph taken by the powder method, show that it belongs to the CsCl set. The edges of the one molecule parallelepipedon are 4·57, 4·50, and 4·50 angstroms.

No measurements have been made on anhydrous sodium iodate, but, from its form and specific gravity, it probably belongs to the CsCl set.

The great similarity between these more complex salts and the simple halides shows that the complex radicles act as single units and the molecule behaves as an electric doublet. Each radicle is surrounded, but not equidistantly, by six or eight oppositely charged radicles according as the crystal is of the NaCl or CsCl type. The question arises as to the possibility of determining the positions of the constituent atoms of the complex radicles, from symmetry conditions and intensity measurements.

The case of cæsium dichloro-iodide, examined very completely by Wyckoff,[4] indicates that this determination is impossible from symmetry considerations, and he attempts to fix the chlorine atoms from his intensity measurements alone, describing his results as very uncertain on this account. Symmetry considerations, following Shearer's principle,[5] show that the $CsICl_2$ molecule should possess a trigonal axis, which is impossible for any static arrangement of the ICl_2 radicle, since chemical considerations of stability, and the shape of the cell, negative the placing of the atoms in a line along the trigonal axis.

Another relevant case is that of the ammonium radicle in ammonium chloride. The radicle as a whole occupies positions in space which determine the crystal symmetry, and the positions of the hydrogen atoms cannot be determined. This conclusion is verified by the study of the ammonium alums.

There seems to be no valid reason for giving to the hydrogen atom alone the negative privilege of self-effacement in symmetry considerations, so long as it occupies space. The fact that the salts containing complex radicles which are considered above are so closely related to the simple halides leads to the conclusion that, for other radicles as well as ammonium, the symmetry is independent of the position of the constituent atoms in the radicle, the latter behaving as a unit. The crystal-forming forces are probably electrostatic attractions independent of any structural axes the radicles may possess.

The occurrence of what has been called ionisation in the simple halides has led to the conclusion that no deduction as to atomic symmetry can be made from their crystal structure. As I have pointed out elsewhere,[6] this "ionisation" probably indicates the presence of heat motion in the form of rotation. In the simple halides the radicles can rotate separately, since there is no molecular bond. In the more complex salts considered above, in which the chemical molecule exists, the molecule apparently rotates as a whole about the electrostatic axis of the doublet, and the positions of neighbouring molecules are probably determined by the sizes of the radicles and pressure considerations, similar to those described by Bartlett and Langmuir,[7] to explain the transition of ammonium chloride from the CsCl to NaCl type.

The Atomic Weights of Zirconium and Hafnium.

IT is just a hundred years ago that the atomic weight of zirconium was determined by Berzelius. The method used, namely the analysis of the sulphate, yielded too low a value for the atomic weight, the same being the case in all the different methods used by his followers. This error was compensated, however, in part by the presence of 0·5 to 2 per cent of a heavy element (hafnium) in their preparations (see NATURE, March 15, 1924). It was only in 1917 that Venable and Bell, when analysing $ZrCl_4$, used a more trustworthy method originating from T. W. Richards's laboratory. The values found by these investigators were appreciably higher than those found by their predecessors, and showed at the same time fluctuations for the values of the atomic weight, greater than should be expected considering the extreme precautions taken and the reliability of the method used.

These fluctuations could not be accounted for at the time of the measurements. After the discovery of hafnium it suggested itself that the variations found by Venable and Bell were due to a varying hafnium content in the preparations used. Through the courtesy of Prof. Venable we have been able to investigate the samples used by him and by Dr. Bell, and have found a hafnium content varying between 0·7 and somewhat above 1 per cent. Taking into account this presence of an element having the atomic weight of about 180 in their preparations, Venable and Bell calculated the value 91·3 for the atomic weight of zirconium. This value is in an excellent agreement with the value (91·25) arrived at recently by Hönigschmid and Zintl (*Zeit. anorg. Chem.* 139, 293, 1924) using a preparation purified from hafnium in this laboratory and found to contain less than 0·02 per cent of this element. It is of great interest that the above numbers coincide closely with the value which can be estimated from experiments with positive rays. Aston found for zirconium the mass lines 90, 92, 94, and a doubtful one at 96, and estimates the atomic weight as 91·4 or 91·2, according to whether the mass number 96 is included as an isotope or not. We may, therefore, be justified in believing that the atomic

weight of zirconium is 91·3 with an accuracy of about 0·1 unit.

While the presence of 1 per cent. HfO_2 in a preparation of ZrO_2 influences the apparent atomic weight by 0·6 unit, the presence of 1 per cent. of ZrO_2 lowers the apparent atomic weight of hafnium by not less than 1·4 units One must thus obtain a hafnium preparation containing a very small amount of zirconium in order to fix the atomic weight of hafnium with an accuracy similar to that reached for zirconium. It was possible some time ago to supply Prof. Hönigschmid with such preparations from this laboratory The values found by him, when analysing $HfBr_4$, for the best preparation were 178·32 and 178·35, and for a less pure fraction 177·78 and 177·80. The samples used by Honigschmid and Zintl were recently very thoroughly investigated by Mr Thal Jantzen by means of the method of X-ray analysis, which when proper precautions are taken is able to give values of high accuracy and offers a simple method of estimating the zirconium content of hafnium preparations The values for the zirconium content of these preparations were found to be 0 16 and 0·57 per cent The values for the atomic weight found by Hönigschmid and Zintl have thus to be raised to 178·57 in the first, to 178·64 in the second case, and we may, therefore, with a probable error of less than 0 1 unit fix the atomic weight of hafnium at 178 6.

Late Palæolithic Art in the Cresswell Caves.

I WRITE as chairman of the British Association Committee, now resuming, by permission of the Duke of Portland, the exploration of the Cresswell Caves where it was dropped some forty years ago by the Rev Magens Mello and myself, to prevent your readers from being misled by the following passage in the third edition of Prof Sollas's book on "Ancient Hunters," p 536

"There is a singular absence of any attempt at art in all the Palæolithic stations of England. The horse figured here [Fig 299] is, I am assured, a forgery introduced into the cave by a mischievous person."

The Cresswell horse was the first proof of the range into Britain of the wonderful art of the French caves, and the discovery made in the 'seventies by myself was published—after a careful scrutiny by Sir John Evans, Sir Augustus Franks, Lord Avebury, General Pitt-Rivers, and other leaders—in the Quarterly Journal of the Geological Society of London It has remained unchallenged for more than forty years, and has passed into the literature of anthropology *Res judicata est* The charge of forgery is not now to be made without clear evidence In answer to a letter asking for this evidence Prof Sollas writes to me that it is based on what he was told "some years ago, I think 1919," by a clergyman since dead, who declined to give names or other particulars. This means that the charge of forgery is founded on gossip without a shred of evidence, and is unworthy of further notice

The Cresswell horse is engraved in fine lines in a style similar to that of the figures of animals found since in the late palæolithic caves of France and Switzerland It is not accurately represented by Prof. Sollas in his Fig 299 This figure is copied from Evans's "Ancient Stone Implements" (2nd edition, p 524), in which my woodcuts were used If the copy be compared with the original it will be seen that the details have been omitted, leaving merely an outline useless for the study of the art of the caves.

Prof. Sollas is equally unfortunate in his sweeping statement that there is no attempt at art in the palæolithic caves of England. Our Committee is now at work at Cresswell, and Messrs. Garfitt and Leslie Armstrong have already recorded the discovery of incised figures of bison and reindeer along with other late palæolithic finds. As the work proceeds it will probably result in further proof that the picturesque gorge of Cresswell Crags was a hunting station of the artistic tribes who followed the wild animals in their migrations from the south of France into Britain, then the north-western region of the great Pleistocene Continent.

The Ages of Peat Deposits.

THE wide interest now taken in the study of peat will, I think, justify further reference to the subject of Dr Pearsall's article in NATURE of December 6 and the letters from Mr. Tonks and Mr Forbes which followed on January 24 It is satisfactory to note that Dr. Pearsall has withdrawn from the obviously fallacious correlation he at first put forward He now, however, makes a second correlation based on the identification of the birch scrub on the peat-covered 25-foot beaches as Lewis's Upper Forest, making the latter Neolithic in age and therefore climatically in conflict with the evidence in the Pennines. This yields him the same result, namely, that climatic deductions from peat and forest beds are untrustworthy.

This second correlation, however, has no more to recommend it than the first. Mr Forbes will, I am sure, bear me out when I say that a few isolated occurrences of birch scrub at a low level are no proof of a forest period. On the contrary, the evidence of the submerged forests indicates that the period of greatest tree growth in the British Isles, *i.e.* Lewis's Upper Forest, antedates the 25-foot beach Dr. Pearsall will, therefore, have to try still another correlation if he wishes to establish his point

May I add to that of Mr. Tonks my appreciation of the admirable work recently done in the Pennines by Dr. Woodhead, Mr. Buckley, and Mr Holmes.

W B. WRIGHT.

Manchester

IN directing further attention to the question of peat deposits, Mr Wright seems to add little to the questions raised He accuses me, however, of basing a hypothesis on the occurrence of isolated patches of birch scrub. I have repeatedly (and publicly) expressed the opinion that the presence of timber in peat can have little significance unless the wood layer is continuous over a very wide area, and I have, indeed, criticised Lewis on the grounds that his "forest layers" did not always fulfil this condition. I may, therefore, be forgiven for finding Mr. Wright's accusation a little amusing It appears to me, however, that his criticisms can only be seriously urged by disregarding completely the use of the words "may" and "might" in my letter (although one of them is italicised), and by failing to attach any significance to the sentence which expresses the opinion that, on whatever they are based, these hypothetical correlations throw doubt on the climatic hypothesis of peat stratification. This is the gist of the letter, to which Mr. Wright's attention may be redirected.

W. H. PEARSALL.

The University, Leeds.

The Mortality of Plaice.

THE letter of Dr. G. P. Bidder in NATURE for January 31, p. 155, on "Constant Differential Growth-ratios and their Significance," raises the very interesting question: Are plaice potentially immortal? In other words, does senile decay occur? This might be decided directly by cytological investigation of old fish, but there is another indirect aspect of the question which my own work on plaice suggests as worthy of being brought forward in this connexion; namely, the differential death-rate of the sexes. Dealing with large collections from two regions, the North Sea and western part of the English Channel respectively, I showed (International Investigations Marine Biological Association, Report III. 1906–8 (1911)) that in each region males were more numerous than females up to the age at which the majority of males become mature for the first time, after which, or soon after which, females begin to preponderate, the number of males diminishing somewhat rapidly

Commenting on this phenomenon I said "The reason for the *rapid* decline in the relative number of males just after maturity might be somewhat obscure if only natural causes were at work. We know, however, that in the breeding season the catch of ripe males by trawlers greatly exceeds that of females on the spawning grounds; and it is possible, as Hefford suggests, that this factor may be the cause of the rapid decline in the proportionate numbers of this sex after maturity is reached" This artificial factor would, however, scarcely explain the whole result, nor would it account for the same phenomenon in the plaice of the Barents Sea, which was practically a virgin fishing-ground when Atkinson investigated it in 1907 and 1908 (Journal of the Marine Biological Association, vol 8, Nos 2 and 5) Then there are many cases of other species of fish and of other groups (cited by S W Geiser, *American Midland Naturalist*, vol. 8, No 7, 1923) in which the same thing occurs, and where there is apparently no suspicion of the unequal incidence in the two sexes of extraneous factors tending to the longer survival of one sex How then are we to account for the difference except by the lesser viability of males? This apparently implies natural death

Dr. Bidder also makes the interesting statement that "the ratio of ovary-weight to body-weight has no relation to age, but only to body-weight; in this as in some other respects, the age of a plaice is not measured by years but by the quantity of food which it has succeeded in assimilating." Among the "other respects" with which I am familiar from personal investigation I may mention the advent of maturity, which is apparently determined by size and not by age. Thus the plaice of the Barents Sea (see Atkinson, *ibid.*) are the same average *size* at first-maturity as the plaice of the central North Sea, but the average *age* at first-maturity differs very considerably owing to the much slower growth-rate of the Barents Sea fish (up to 1908 at least), due ostensibly to overcrowding and limited food supply. The same general cause would also account for the fact that while the average *size* at first-maturity of the North Sea plaice soon after the War (during the latter years of which restrictions on fishing produced overcrowding) was the same as in pre-War years, the average *age* at first-maturity was considerably higher.

Coal Resources of Alberta.

I SHOULD like to use the medium of your pages to ask that, when scientists and others sit in their offices or studies at home, to write about the resources of the outlying portions of the British Empire, they at least consult up-to-date and official reports on their subject. I hesitate even to suggest that they might restrain their pens either from modesty or from fear of ridicule when their information is only second-hand.

A case in point is a recent volume on "Fuel" in the "Resources of the Empire" series The description of the coals of Alberta, which have been estimated to constitute more than 60 per cent of the coal resources of the British Empire, is allowed only one and one-half pages out of the 63 pages in this section of the book The compiler takes most of his statements from a report published in 1913, and now much out-of-date But, to make matters worse, in a drastic condensation of the earlier report, he retains all or most of the mistakes and adds others The result is laughable to any one who knows anything of the subject

The Canadian Government at Ottawa has published many reports on the natural resources of the country, and the Scientific and Industrial Research Council of Alberta, during the past five years, has published ten reports on the resources of the province These reports are readily available in England, and requests for information receive attention There is therefore no excuse for the publication in England of out-of-date and incorrect statements

EDGAR STANSFIELD,
Honorary Secretary,
Scientific and Industrial
Research Council of Alberta.

Edmonton, January 30.

Pliocene and Pleistocene.

As you quote in NATURE of February 21, p 278, from a note of mine printed in No. 6 of *Natural History* (American Museum of Natural History), will you allow me to state that the note quoted was not submitted to me in proof by the editor of *Natural History* The part you quote embodies a serious misprint The words "distinguished by the marine 'Pliocene'" should read "distinguished by the name 'Pliocene.'" As I am writing further on the application of the terms "Pliocene" and "Pleistocene" to various deposits in East Anglia, I should like to remove at once this unfortunate misrepresentation of my views.

E RAY LANKESTER

Mercury Helide.

IN a recent note (NATURE, December 13, 1924, p. 861), dealing with the formation of mercury helide, mention was made of a plan which was being perfected for a quantitative analysis of the compound. The analysis has now been completed, with the result that 210·79 parts by weight of mercury were found in combination with 4·18 parts by weight of helium. Hence 200 6 parts by weight of mercury combine with 3·98 parts by weight of helium The simplest formula for the helide is therefore HgHe.

A detailed account of the work upon which this conclusion is based, will, I hope, be published shortly.

The Control of the Tsetse Fly Menace.

By C. F. M. SWYNNERTON
(in charge of Tsetse work in Tanganyika Territory).

TSETSE-FLY problems may be divided into three —the problem of *G. palpalis* and the rain-forest tsetses, that of *G. tachinoides* and that of the savannah or "bush" tsetses belonging to the *morsitans* and *fusca* groups. These, as Major Church showed well in his recent article in NATURE, January 31, inhibit the development of vast areas in Africa, and members of the *morsitans* group are the carriers of Rhodesian sleeping sickness. It is to the control of the bush tsetses that I shall refer in this article (though the broader principles laid down would refer to all), and I shall describe in particular the methods and ideas that we are employing in our fight against them in Tanganyika. These may be understood best if I say that I have from the first felt that if we are to attack the tsetse-fly economically as well as effectively, we must do so in the main by the mere diversion and regulation of agencies already in existence—always, of course, with the fullest knowledge of and regard to the habits of the particular species we are fighting.

This implies that the natives would be taught to understand and take part in the solution of their own problems, and that natural agencies, such as grass-fires, flooding and exceptional seasons, would be harnessed. In a report to the Portuguese Government (*Bull. Ent. Res.*, vol. xi. pt. iv. pp 315-385) I laid special stress on the fact that "settlement properly planned will protect itself," on the utility of offering inducements to natives to settle in places, perhaps quite limited, where previous ecological investigation should have indicated that their presence will lead to control of the fly, on the part that European settlement on a sound agricultural basis might be made to play if clearing of the crucial spots were made a condition of occupation and the farms were small enough, and on the probable great value of postponing the annual grass-burning, usually worse than useless, to the end of the dry season (October), and then carrying it out under chosen conditions and in a thoroughly organised fashion.[1] I also emphasised the necessity for studying means of consolidating clearing or, in the absence of consolidation, the need, in a great fly-belt, for providing fly-proof barriers up to which to work; and, in a later report (*Bull. Ent. Res.*, vol. xiii., pt. iii. pp. 317-370), I sketched the scheme which has since been put into operation in Tanganyika Territory, and will be described briefly here.[2]

It should be noted, first, as regards "settlement properly planned," that the bushless cattle-areas of that Territory are, in very large part, "culture steppe," to borrow, provisionally, a German term. That is, they are kept free of bush and, thereby, of tsetse-fly, almost solely through the presence of sufficiently (not excessively) closely-dotted villages with their chopping for firewood, building and cultivation and the browsing of their numerous stock. On the whole, settlement and bush, man and fly, are sharply segregated. It is hoped that by encouraging this form of settlement in the far greater areas in which the natives *all* live dotted through the bush, pestered with tsetse and subject to other serious disabilities, we shall extend segregation and obtain what will be, for practical purposes, a control of the fly. This form of settlement—implying concentration of organisable labour, a safe base from which to extend, and a breeding centre for population which, being accessible, is capable of receiving assistance from us—is in any case a necessary preliminary to all measures of a large nature against the tsetse in the bush—that is to say, to *reclamation*. The production of it throughout the Territory will be gradual, and in certain parts it may prove to be impracticable, but appreciable success is already in places attending our initial propaganda.

Concentration accomplished and the natives in our new culture steppes assisted to become the possessors of cattle (for these are necessary in order to "anchor" them), it will remain for them to protect themselves against encroachment of the bush and the fly and to expand their fly-free grazing *pari passu* with the increase in their cattle. This, with tact and propaganda, will be done as we have already begun to do it in Shinyanga—through sheer clearing (as last year), for this appeals to the native, or better, through more discriminating measures which will be carried out by the people themselves under our guidance during a few days each year. Here I would say that our victory in Shinyanga lay not in our large clearing of ground—many people have cleared ground (and then let it go back to bush and tsetse)—but in the successful teaching of a native population to tackle its own problems. Stiebel, McMahon, Scupham are my administrative collaborators to whom the credit for this is chiefly due.

Thereafter, as population increases (and we would help it to increase by means of propaganda in hygiene), the scheme is that we should so guide the directions of expanding settlement as to bring into being coalescence, and thereby complete our fly-proof barriers and break off our blocks—the latter corresponding, let us say, in width with so small a fly-belt as that of Zululand. These, being of more manageable dimensions than our entire belt, would next be attacked individually in order to obtain final security and room for the freest development.

What methods are we to apply to the blocks? Lamborn's fine work in the breeding and release of parasites has been mentioned by Major Church. This, in places, might prove a useful contributory measure. Shircore, in an admirable little paper published in 1914, suggested, first, the concentration of attack on the dry-season centres of *G. morsitans* (which would first, he suggested, have been isolated by clearing from the rest of the bush and finally be cut down themselves); and, secondly, for the further controlling of the movements of the fly (which can be done, he considers,

[1] I based this recommendation primarily on more than fifteen years of experiment and observation as to the results on woody vegetation of grass-fires lighted year after year in different months, but suggested that deferred fires would also have the other effects—on the pupæ and as to the driving of the fly on the wing into unburning thickets, which would themselves gradually be destroyed—which I shall describe below. Shircore, in 1914, included grass-burning postponed to late July or August, for the clearing up and driving of any flies still scattered, amongst his measures of attack on the dry season centres of *G. morsitans*. Lloyd and Johnson have suggested that, long grass being inimical to breeding, the postponement of burning may be useful also for the prolongation of this unfavourable condition.

My experiments in Shinyanga will be described in detail in the *Bulletin of Entomological Research*.

even by narrow barriers), "the splitting up of fly-belts near villages and along main routes by forest destruction and burning." This, with the extension of agriculture, the clearing of villages and the attacking of the fly-centres, would ultimately, he thought, limit fly to areas which need not be entered by the natives. I doubt whether, short of such concentration of population as would produce "culture steppe," these measures could maintain safe segregation in any considerable belt; but they are thoroughly sound in principle and probably roughly represent a part of the means by which the relatively small belts of South Africa were unintentionally cleared of fly by the early settlers. Under such conditions I propose to use them freely.

Jack has experimented on a large scale in the destruction of game—but while, here and there, the checking of particular movements, large or small, of game animals may, if it is also feasible, be very necessary, no one wishes to exterminate our wonderful African fauna, a heritage of the Empire, of posterity, and of the scientific world, if we can control the tsetse otherwise. Our first results in Tanganyika lead to the very strong hope that we can, at least in the type of belt in which I have worked chiefly of late (Acacia-bush with *thickets* as the keynote to the fly's control, much like the fly-bush seen by me in Zululand); and suggest that we should wait a little longer before we commit ourselves finally anywhere to counsels of despair in the form of war against the game [3]

I have mentioned my own views already on the utilisation of man-power and the grass-fires and on discriminative clearing, and I think that the diversion of native energy and settlement—or European energy and cultivation where that is present—to the destruction and breaking up merely of the locally-important types of thickets, is likely to be a most valuable measure, because thickets are the chief breeding place of most species of tsetse and a refuge for all during fires. I am employing this already in conjunction with late grass-burning.

As regards the latter, I demonstrated last year (and, concerning certain points, many years previously) the correctness of the view stated in my Portuguese report, that postponed and organised grass-burning is capable, where the grass and the dry season are long enough, of destroying small woody growth and numbers of the smaller thickets, logs and (to judge from a comparative count obtained at Shinyanga) pupæ, and of driving the flies before the fire in great numbers into previously burned patches and such unburning thickets as are as yet uncleared. Our work suggested that in these places they can be exterminated (given the labour) by sheer catching on a great scale by hand and otherwise before they disperse. There can be little doubt also that by means of October grass-burning Father Cirvegna, a missionary in the Iringa district, has cleared of fly (*G. morsitans*), progressively but completely, an area a dozen miles in diameter in three burnings. The measure is not applicable everywhere.

[3] I may here correct an error that has slipped into a quotation of Major Church's from a conversation with myself—undoubtedly through my not making myself clear. It is by no means the whole of the Dar-es-Salaam district that is "gameless," and bush-pigs are present in any case. The point is that bush-pigs, by any methods now known to us, are, I believe, inexterminable in certain tsetse-infected types of woodland that cover great areas of Africa: and that, from observations made, I consider that these animals can alone support populations of fly sufficient to preclude the keeping of cattle.

An exceptional season appears to have been responsible for the disappearance of the fly in 1921 from some of the out-jutting portions of the Shinyanga belt. Had there existed fly-proof barriers between these and the main belt, they would not have been re-stocked. It is thus, and for the accentuation of the effect of late grass-burning, once this is installed as an annual custom, that I suggest that we shall "harness the exceptional season" for the clearing of some of our blocks.

Finally, the verification by Harris of views held by him (for example as to the possibility of isolating tsetses in particular pieces of bush until, as I understand it, they starve) is likely, when it comes, to help greatly.

I am experimenting also in Shinyanga as to consolidation of ground gained. We are offering inducements to natives to settle where their activities will be of use, introducing a rule that villagers should keep down young shoots from cleared growth round their villages, experimenting in the encouragement of the keeping of goats for their browsing, trying to induce people in culture steppe to dig up stumps for firewood rather than make journeys to the bush for it, and experimenting in cheap methods of killing woody growth. The encouragement given by our Department of Agriculture to the use of ploughs by the natives is helping me, for ploughing entails the removal of stumps, and we are diverting so far as possible large-scale cotton culture by means of ploughing to the actual ground I am clearing. The replacement of great thicket-areas by high forest (in this form, an idea of Fiske's), the safeguarding of roads, the means of reducing the carrying of fly into contact with cattle by man, and the testing of three important questions in connexion with the game, including its possible utilisation as an ally in our fight with the tsetse, are amongst the further experiments which are already in progress or contemplated.

In short, with the very hearty co-operation of the other Departments and of the District Administration, I have put into effect and, I think, begun to justify the view, that we can now best advance our knowledge of how to fight the tsetse by taking a definite large area or entire Territory and applying to it, without stint of necessary funds and labour, all ideas and knowledge that have been gained hitherto, and all further knowledge we yet shall gain, in a large-scale experiment in control by means (preferably) of reclamation officers working hand in hand with research officers. The latter are still needed for expert "survey," for the many points which will come up for investigation as we go along, and because, for economical and effective work, our knowledge of our flies' habits and habitats must be absolute; and, should funds become available, they will be needed in some numbers, in order that, as they master thoroughly the details of the problem and the work in the field (which it would take new men, unattached, some years to do), many may pass on from the earlier centres to other parts of Africa and assist in making the campaign general. Especially is needed a large fund to meet the various expenses of a scheme which shall provide for this gradual development of large-scale experimentation in actual control under all African conditions; that is, at the stage we have now reached, the right method of research.

The Phylogenetic Classification of Flowering Plants.

By JOHN PARKIN.

THE epithet, phylogenetic, in the above title might be considered superfluous, as all biologists are agreed that a taxonomic arrangement of any group of plants or animals should, so far as possible, follow evolutionary lines; after that, its convenience should be considered. Strange to say, up to the present, no arrangement of the Flowering Plants (Angiosperms), which has been generally adopted in text-books or used for floras, merits the term phylogenetic—hence the insertion of the word in the heading to this article.

Of the two chief classifications in use at the present time, that of Bentham & Hooker never outwardly professed to be a phylogenetic arrangement; while that of Engler, though apparently launched as such, has proved unworkable from the evolutionary point of view, and bears the impress of being artificial in its main contention, namely, the primitiveness of the apetalous unisexual flower of few parts. Surely, then, the time is ripe—some would say long overdue—for the introduction of a new system embodying up-to-date views respecting the evolution and possible origin of the flower. A strong movement in this direction is being taken by Mr J Hutchinson of the Kew Herbarium, and a series of papers by him, entitled "Contributions towards a Phylogenetic Classification of Flowering Plants," are appearing in the *Kew Bulletin*.[1] It is the purpose of this article to invite the attention of botanists to these papers, and at the same time to review briefly the general position and trend of this department of botany.

Kew has never adopted Engler's system. It has hitherto remained faithful to that of Bentham & Hooker as expressed in their classical work the "Genera Plantarum." But at last it shows unmistakable signs of breaking away and of inaugurating a new arrangement on logical lines. As it controls largely the systematic botany of the Empire, such a system is bound to make headway, so it is incumbent on those botanists who are interested and sympathetic to give it their attention and helpful criticism, in order that it may benefit thereby before it becomes too stereotyped. A new system cannot be fully worked out all at once. Hutchinson's method of publication by a series of preliminary papers gives ample opportunity for this kind of criticism, and we are sure that such comments will be much welcomed. He has already enunciated his principles and dealt in detail with some of the important families[2] composing the Ranales upon which his system is based, and last year he published his proposed rearrangement of the orders (cohorts) and families constituting the Archichlamydeæ of Engler (the equivalent of the Polypetalæ and Apetalæ combined of older classifications). These papers are not only worthy of the attention of the taxonomist, but also of the general botanist. They infuse new life into a department of botany which at times is apt to savour too much of the kind of material with which the systematist usually deals.

It is well to remember that, prior to the publication of "The Origin of Species," systematic botany was under the influence of the dogma of the constancy of species. Since systematists then adhered to the belief that the different forms of plants were special creations, the idea of primitiveness was not involved—it had no meaning. Consequently it was largely optional as to which group was given the initial place in a system. Two chief tendencies, however, are noticeable with respect to the Dicotyledons—one the placing of plants with incomplete flowers lacking petals (the Apetalæ) first, and the other, the putting of the Ranalean families (Ranunculaceæ, Magnoliaceæ, etc.) into this prominent position. One may be said to have culminated in the classification of Engler and the other in that of Bentham & Hooker. The former system in a measure owed its initiation to Brongniart, who in 1843 suggested that the apetalous division of Jussieu ought to be abandoned on the ground that these flowers are an imperfect state of polypetaly. This was a remarkable step forward on the part of this French botanist, considering it was ventured at a time when the principle of evolution was not generally accepted. The German school later, while putting into practice to some extent Brongniart's suggestion, *e.g.* in uniting the apetalous Chenopods with the petalous Caryophylls—the stock example—made no attempt to interpolate the whole of the apetalous families among the Polypetalæ; but instead diverged on novel lines by postulating, or at least inferring, the primitiveness of unisexual flowers of few parts, such as we find in the catkin-bearing trees and Casuarina.

Bentham & Hooker made no attempt to apply Brongniart's principle. They adopted the Candollean classification, modifying it in certain respects. De Candolle was the first to commence a dicotyledonous sequence with the Ranalean families, and Bentham & Hooker followed suit. They both treat the apetalous families as a sort of miscellaneous appendage, after dealing with the whole of the Polypetalæ and Sympetalæ. It is interesting to note that no phylogenetic significance was attached to the position assigned to the Ranalean families.[3] Intuitively they appear to have alighted upon the primitive group.

Hutchinson's aim is to reconcile, as it were, the two opposing systems at present in use, on one hand, by taking the Ranalean families as his base and, on the other hand, by making full use of Brongniart's principle. He considers such a system, broadly speaking, phylogenetically sound, and with this the present writer is in agreement.

Among British systematists Engler's system has met with tardy acceptance. The conservatism of Kew has probably been the restraining influence—a conservatism which now appears justified. In universities, however, it has by now been generally adopted, apparently without criticism. Doubtless Engler's great name, coupled with the publication in association with Prantl of that colossal, finely conceived and beautifully illustrated work "Die Natürlichen Pflanzenfamilien," which marks an epoch in botanical literature, prevailed upon botanists to accept the

[2] Ranunculaceæ, Winteraceæ (detached from the Magnoliaceæ) and Annonaceæ.

[3] See, in this connexion, a letter dated May 13, 1907, from Sir J. D. Hooker to Dr. Newell Arber, reproduced in "Life and Letters of Sir J. D. Hooker" (Leonard Huxley, London, 1918, vol. ii, p. 22).

system. It appears to me to be a most difficult one upon which to frame a course of instruction in what is known, for want of a better term, as systematic botany. Perhaps, though accepted in the abstract, it is largely ignored in the class and lecture-room! But there is the self-taught botanist to consider, and he has only text-books on Englerian lines for his guidance.

Let us glance at the difficulties in the way of regarding Engler's system as even remotely phylogenetic. It is based essentially on the character of the perianth: the mere fact of relying on one organ for his sequence arouses suspicion as to its naturalness. He commences with families possessing flowers without a perianth or with sepals only, passes to those with a petaloid perianth, and then to those with a definite calyx and corolla There is no evidence of the perianth arising in this *de novo* fashion, as outgrowths from the floral axis, as presumably is the supposition. Besides this, we are committed to the difficulty of deriving the hermaphrodite from the unisexual flower. In both cases the evidence—and there is an abundance—points the other way, namely, that the absence of the perianth or of one set of sexual members is due to reduction. In regard to the catkin families (Amentiferæ) and the like, with naked or apetalous flowers, where obvious links with petalous hermaphrodite forms are not to the fore, surely it is simpler on circumstantial evidence to look upon these flowers as very reduced, than to view them as being primitive in character. Further, it is to be noticed that such flowers are grouped in dense and often complicated inflorescences—an arrangement which cannot be taken as primitive

A considerable controversy has centred around the supposed primitiveness of the Amentiferæ on other grounds than the character of the flower. This has arisen in part through Treub's classical researches on Casuarina published in 1891, and in part through the hope of deriving the Angiosperms from the Gnetales through this group. The Amentiferæ consequently received a considerable amount of attention, especially as regards the internal structure of the ovule. All attempts, however, to connect the catkin-trees with the Gnetales have proved abortive, or at any rate far from convincing. Treub's discovery of the peculiar way (chalazogamy) in which the pollen-tube penetrates the ovule in Casuarina, though hailed at first as a primitive character of prime importance, can now only be regarded as secondary and of little or no phylogenetic significance. The Amentiferæ may possess some primitive features in the ovule and in the structure of the wood, but they do not appear to have a monopoly of these. In one point the Magnolian group surpasses them, for certain of its genera lack vessels in the wood, and so are gymnospermous in this respect. It would thus appear quite feasible to regard the Amentiferæ as having come as an early offshoot from Ranalean stock along reduction lines. There is some evidence for their affinity with the Rosales generally, and with the witch-hazels (Hamamelidaceae) in particular. Hutchinson favours this view.

In certain quarters in which the Amentiferous flower has been accepted as primitive, the Ranalean flower has also been admitted as a primitive type. The logical outcome of such an expression of opinion would surely be to infer a polyphyletic, or at least a diphyletic, origin for Angiosperms. But there are grave difficulties in such an inference. At the present time I venture to think that the vast majority of botanists regard the Angiosperms as monophyletic; that is to say, an interrelated assemblage of plants which have arisen from one source. Apart from other considerations, one has only to dwell upon the unique type of embryo-sac and the same kind of stamen (microsporophyll) prevailing throughout the group to be convinced of this. Ruling out, then, the possibility of a mixed origin for Flowering Plants, the derivation of all forms of flowers from the Ranalean pattern,[4] especially as exhibited in Magnolia and its allies, would appear to be the only feasible one; thus affording a basis upon which to erect a phylogenetic, or at any rate a logical, system of classification.

The Monocotyledons have so far not been mentioned. Though various views have been held in the past regarding their relationship to the Dicotyledons, there is now a consensus of opinion that they have had a dicotyledonous origin. In other words, their ancestors possessed seedlings with two seed-leaves (cotyledons). How the monocotyledonous seedling with its single seed-leaf arose from the dicotyledonous one is still a matter of dispute. The Monocotyledons must perforce have branched off at a very early period, as the two groups are traceable back to rocks of about an equal antiquity

It is then on morphological rather than geological evidence that the dicotyledonous derivation of the Monocotyledons is favoured. It is difficult to interpret otherwise their peculiarities, such as the single cotyledon, lack of cambium and style of leaf Consequently, in a new system of classification which professes to be phylogenetic, they should follow, and not precede, as Engler has them, the Dicotyledons Hutchinson, I believe, intends to place them so. Two points now arise which affect their arrangement. Have they had a single or plural origin from the Dicotyledons? Though no precise answer can yet be given to this query, the present writer sees no cogent reason for regarding them as other than a natural self-contained group. Then it may be asked from what dicotyledonous assemblage of plants can they be derived? The floral features in common between some of the water-lily family (Nymphæaceæ) and the Helobieæ (water-plantain, flowering-rush, etc.) suggest something deeper than mere parallelism. It may not therefore be unduly straining affinities to derive the Monocotyledons from the Ranalean plexus The Helobieæ can then be treated as the primitive group, at any rate so far as floral features are concerned. The question of the origin of the Monocotyledons is largely bound up with that of the habit of their immediate ancestors Henslow, years ago, suggested an aquatic origin, and though this was seriously challenged by the late Miss Ethel Sargant in favour of a geophilous origin, it cannot yet be dismissed. The truth may lie somewhere between. Just as in the Dicotyledons, lines of both advancement and reduction with respect to the corolla (petals) can be traced. One of the former has ended in the Orchids, with their

[4] A hermaphrodite flower, in short, with its members indefinite in number, free from one another, borne spirally on a conical axis and arranged in a definite sequence on this axis, namely, proceeding from below upwards, first perianth members with no clear separation into sepals and petals, then stamens, and finally carpels.

extreme specialisation for insect-pollination, and one of the latter in the Grasses, well adapted for pollination by the wind. Disregarding the teleology, we believe there is a substratum of truth in the following lines:

They tell us that the homely corn that grows,
From russet stem and leaf, our daily bread,
Was once a lily; which by various steps
Of menial work, became degraded thus;
It left its high-born sisters in their robes
Of gorgeous idleness to clothe itself
In this plain dress for common household use.
Its bright-hued petals, nectar cup, and store
Of fragrance sweet, that insect lovers wooed,
It sacrificed; and only wandering winds,
That have no sense of beauty or delight,
Now woo its sober blooms with heedless sighs.
But for this noble humbling of itself
God has more highly honoured it, to be
The chief support of human beings, made
In His own image—rulers of the world.

(To be continued.)

Biographical Byways.[1]

By Sir ARTHUR SCHUSTER, F.R.S.

10. HERMANN HELMHOLTZ (1821–1894), HEINRICH HERTZ (1858–1894), AND RÖNTGEN (1845–1923).

THE names of Helmholtz and Hertz remain connected together in my mind probably because, when I met them towards the end of their lives, the conversation with both mainly turned on the nature of cathode rays. Hertz adhered to the idea that they consisted of vibrations, while Helmholtz from the beginning stood up for the corpuscular theory, and was rather sore that the idea did not originate in his own laboratory. During the few months I was working there, at the end of 1874, Goldstein was engaged in the important researches which the Royal Society has recognised by the award of the Hughes Medal. His experiments, which showed that the rays emanating from a cathode were strongly repelled by an adjacent parallel electrode, were sufficient to convince Helmholtz that the rays consisted of a projection of negatively electrified matter, but Goldstein did not fall in with this view. "Of course," said Helmholtz to me a few years later, "as soon as Stokes became acquainted with Crookes's experiment he guided him into the right path."

In his early years Helmholtz seems to have been very sensitive to criticism. Roscoe used to relate how he found him once in great distress, complaining that his whole scientific career was endangered because some one had thrown doubt on one of his conclusions.

The Physical Laboratory of Berlin in 1874 contained only three or four rooms, with about a dozen students engaged in researches on a number of subjects mostly suggested by Helmholtz. In his daily rounds he used to discuss scientific problems freely with each in turn. He was as quick as Kelvin in being able to shift his mind quickly from one subject to another, but, in contrast with Kelvin, there was always a good deal of the *Grand Seigneur* in his attitude, and the title of *Excellency* bestowed upon him was borne with great dignity. He relaxed to some extent in his annual visits to Pontresina, where I received much encouragement from him in my early attempt to form some consistent theory of the passage of electricity through gases.

Her Excellency—his second wife, and a member of the South German aristocracy—was fond of society and gave weekly musical parties at their home in Berlin. She was of a highly strung and nervous temperament. During one of their visits to England they were staying with Roscoe at Manchester, and one morning she came down to breakfast complaining that she had been very ill during the night. She woke her husband, saying: "Hermann, I am going to die." "That is easier said than done," replied Helmholtz, turning round to sleep again. At one of his visits to Roscoe, he was accompanied by his daughter. The conversation turned on the possibility of flying. "It would be beautiful," said Miss Helmholtz; "one could escape so easily from one's chaperon; but then perhaps girls would be put into cages."

The intimate relations which Helmholtz maintained with Kelvin are referred to in the biography published by Königsberger. I may quote here the passage from a letter written by Helmholtz to his wife while on a visit to Lord Kelvin:

> "The former (James Thomson) has a good brain with clever ideas, but he will not listen to anything except about engineering and talks about it at all hours, day or night, so that no other subject of conversation has a chance in his presence. It is amusing to watch each of the brothers (William and James) insisting on explaining something to one another, and neither of them listening to what the other says. But the engineer is more persevering, and generally gets his own way.
>
> "In the meantime I have seen a number of new and ingenious appliances of William Thomson's, and had two interesting days here in consequence. But Thomson's thoughts follow each other so rapidly, that one can only obtain the necessary explanations about the working of his instruments, etc., by a series of questions to which it is difficult to get an answer. How his students can understand him is beyond me, as they cannot permit themselves to make the efforts to keep him to the point, which I could venture upon. All the same, a number of students were working in the laboratory and seemed to know what they were doing. . . . Thomson's experiments did for my new hat. He set a heavy metallic disc, balanced on a point, into rapid rotation, and in order to show me how the disc became immovable by the spin—he struck it with a hammer. The disc revolted against this treatment and flew off to one side, projecting the iron stand in the opposite direction. The stand split my hat and carried it away. The disc happily did no damage beyond breaking some glasses."

As is well known, the original suggestion that Hertz should undertake the experimental demonstration of the propagation of electrodynamic waves according to Maxwell's theory came from Helmholtz. The research could be undertaken only by one who possessed exceptional abilities both on the theoretical and experimental

[1] Continued from p. 306.

side. The merit of the execution belongs to Hertz alone. Towards the end of 1888, he communicated his first decisive success in obtaining waves of comparatively short length so that he could, by means of a parabolic mirror having an aperture of two metres, form a parallel beam and confirm previous results. Helmholtz wrote in answer: "I was much pleased with your latest feat. It concerns things at the possibilities of which I have nibbled for years in the hope of finding a hole by which to enter. I am therefore familiar with your line of thought, and its great importance is quite clear to me" In the same year Hertz had the choice of accepting a professorship at Berlin or Bonn, the vacancies occurring through the deaths of Clausius and Kirchhoff. Hertz decided for Bonn, and Helmholtz, approving the choice, writes: "Whoever is still able to carry out extensive scientific work is well advised to keep away from large towns" The great appreciation of Hertz's work by Helmholtz is shown by the unusual course he took in proposing the posthumous award of a certain prize to Hertz. He justified the proposal on the ground that it may "discharge a debt of the nation, inasmuch as Hertz during his lifetime had been much less honoured by his countrymen than by other nations"

In my own intercourse, I found Hertz to be a man of extreme modesty. During one of my visits to him, he received the news of some distinction the Academy of Sciences of Vienna had bestowed upon him. He seemed worried by it. "Too many honours," he said, "are as bad as too few. They do not add to the pleasure and only create jealousies" With regard to the fundamental question of cathode rays, he attached great importance to an experiment he had made, which showed that they could pass through gold leaf, and looked upon this as telling in favour of waves; to which I could not agree.

I am told that in early youth Hertz gave expression to weird ideas with regard to possible happenings if some of the ordinary circumstances of life were changed.

It is sad to think that the illness which led to his death was probably aggravated, if not caused, by the unsanitary state of his laboratory, which, as I am told, had been built and used as a hospital for certain contagious diseases.

The succession of experimental discoveries leading, through Hertz, to the important researches first of Lenard and then of Rontgen is well known. I never spoke to Röntgen, and hearing of his presence in another hotel during one of my visits to Pontresina, I called on him. He was not at home, but I saw his wife, who received me in a friendly manner. The call was never returned, though amends for this want of courtesy were made a few months later. Returning to Manchester from a short Christmas holiday at the end of the same year, I called at the laboratory on my way home from the station On looking at the accumulated correspondence, I opened a flat envelope containing photographs which, without explanation, were unintelligible Among them was one showing the outlines of a hand, with its bones clearly marked inside. I looked for a letter which might give the name of the sender and explain the photograph. There was none but inside an insignificant wrapper I found a thin pamphlet bearing the title "Über eine neue Art von Strahlen," by W. C. Rontgen. This was the first authentic news that reached England of the discovery of the so-called X-rays. I sent a translation of the paper to NATURE, where it appeared on January 23, 1896.

Obituary.

SIR EDWARD THORPE, C.B., F.R.S.

ALTHOUGH Sir Edward Thorpe had been unwell for some considerable time, yet his well-known energy and virility were so remarkable that it came as a shock to his many friends to learn that he had passed away on Monday, February 23, at his beautiful Devonshire home by the sea, Whinfield, Salcombe. It was an ideal residence in his retirement, for he could there enjoy his favourite relaxation of yachting, and take any one of his three yachts out to sea for a sail just as readily as taking a walk, which the hilly roads and paths of South Devon had latterly rendered a matter of difficulty for him.

Carrying my mind back to the year 1885, when I had already been two years as a Royal Exhibitioner at the Royal College of Science, South Kensington, I remember the gratification with which we students learnt that our retiring professor of chemistry, Sir Edward Frankland, was to be succeeded by Prof. Thorpe, whose reputation at the Yorkshire College, Leeds, had gone before him. I had previously studied under Sir Henry Roscoe at the Owens College, Manchester, where Dr. Thorpe had held his first appointment as demonstrator on Sir Henry's staff, and this fact, together with a personal introduction to the new professor from the latter's father-in-law, Dr. John Watts, proved a bond of attachment, which, after my third year as student, but working in the research laboratory, led to collaboration with Prof. Thorpe in several years of research on the oxides and other compounds of phosphorus, and to a demonstratorship and lectureship which lasted eight years, indeed, until Sir Edward, in 1894, left South Kensington to become Principal of the Government Laboratories

Sir Edward was born in the Harpurhey suburb of Manchester on December 8, 1845, his father, Mr George Thorpe, having been a merchant of that city. At the close of his student days at the Owens College he went to study under Bunsen at Heidelberg, carrying with him a letter of introduction from Prof. Roscoe, who had himself been a pupil of Bunsen. Moreover, young Thorpe was entrusted with a present from Roscoe to Bunsen, namely, some well-formed crystals of potassium and sodium, which Roscoe had placed in separate bottles under rock-oil, as usual with the alkali metals. In the throes of packing, the young student economised space by placing both metals in one of the two bottles, the crystals being sufficiently different to be distinguishable. After presenting his letter, he duly brought forth the bottle, removed its paper covering, and ceremoniously presented it to Bunsen as containing unique specimens of potassium and sodium crystals. The great chemist looked hard at the bottle and then at his visitor, who then first realised that something was wrong. For, instead of metallic crystals beneath the rock-oil, there

was nothing but a shining liquid resembling mercury. He was beginning to fear that the great master would suspect a practical joke, of doubtful taste, when suddenly Bunsen's face lighted up with a great smile, and he told the would-be new disciple that his first research should be the investigation of this new liquid; he then welcomed him heartily to Heidelberg. The sequel revealed no joke, but the important new fact that sodium and potassium unite to form an alloy, which is liquid at the ordinary temperature, and closely resembles mercury in appearance.

While at Heidelberg, Thorpe had Victor Meyer for both laboratory companion and lodgings partner, so that the well-known great friendship between them dates from that time. After taking his Ph D. degree, Thorpe spent a short time in the laboratories of Bonn, after which he returned to Manchester and took up his duties as demonstrator under Roscoe

In the year 1870 two important events occurred in Thorpe's career, namely, his first professorship in chemistry, at the Andersonian College, Glasgow, and his marriage to Caroline Emma, the daughter of Dr Watts, chairman of the Lancashire and Cheshire Institutes and of the Manchester School Board, and one of the ablest of the pioneers of higher education. In 1874 came the call to the newly established Yorkshire College, Leeds, where he made the chemical department renowned for its efficiency and its output of original research. His painstaking and highly accurate determinations of the specific volumes of liquids of definitely related chemical composition, involving new and refined modes of determining their densities and thermal expansions, led to very important conclusions concerning chemical constitution, and he was elected a fellow of the Royal Society in 1876

On taking up his appointment to the chair of chemistry at South Kensington in 1885, Thorpe suggested to me a research on the oxides of phosphorus, especially with the view of identifying, or if necessary of discovering, the lower oxide, supposed to be P_2O_3 This oxide had really not hitherto been isolated, for the supposed descriptions of it turned out eventually to be quite absurdly erroneous. The professor's first instruction, however, was one which greatly impressed itself at the time, and one which might with great advantage be more generally followed in commencing a research: it was to spend several days in studying and abstracting all the known literature on the subject, from both books and original memoirs.

This research extended over six years, and resulted in the publication of four joint papers. The first paper, published in the Journal of the Chemical Society in 1886, concerned an altogether new oxide of phosphorus, the tetroxide P_2O_4, which we obtained in excellent crystals instead of the expected P_2O_3 for which we were searching The second paper was published in the same journal in 1890, and described the isolation and eventual successful determination of the constitution and properties of the so-called trioxide It proved to be a white waxy solid, melting to a colourless liquid at summer temperature (22° C), and boiling, in an inert atmosphere, undecomposed at 173°, and affording a vapour density which indicated precisely the double formula P_4O_6 and not P_2O_3. The third paper, also in the same journal, was published in 1891, and described a number of interesting reactions and additive compounds of the new phosphorous oxide. The fourth paper gave further details of one of these addition compounds, phosphorus sulphoxide, $P_4O_6S_4$, in preparing which on several occasions very lively and dangerous explosions occurred, one of which left the nearest of us on the floor This fourth paper was contributed to the newly projected *Zeitschrift für anorganische Chemie*, being the first paper in the first number published (February 27, 1892) of that journal.

One of the most satisfactory things about the results of this research was the establishment of the fact, by the kind collaboration of the late Sir Lauder Brunton, that the oxide P_4O_6 was the cause of the necrosis of the jaw from which workers in match factories so frequently suffered. The knowledge gained in the research was eventually the means of entirely avoiding the production of the oxide during the manufacture of matches, and consequently brought about the total disappearance of this terrible disease

During his tenure of the chair at South Kensington, Sir Edward Thorpe carried out the determinations of the atomic weights of gold and silicon, in collaboration with Dr. A. P. Laurie and Mr Young respectively; and also a prolonged research on viscosity with Mr. J W. Rodger, which formed the subject of the Bakerian Lecture to the Royal Society in 1894. The wonderful delicacy and dexterity of manipulation manifested in these researches was even more fully exemplified in the research on the atomic weight of radium, which was carried out by Sir Edward at the Government Laboratory, and formed the subject of his second Bakerian Lecture in 1907. He also carried out at South Kensington researches on some volatile fluorine compounds in collaboration with Mr. Rodger and with Mr. Walter Kirman.

A further important research of a totally different kind was the magnetic survey of the British Isles, which Sir Edward commenced while at Leeds and continued when at South Kensington, in collaboration with Sir Arthur Rücker, who was similarly transferred from Leeds to South Kensington as professor of physics. The writer has some special knowledge of the immensity of this work, as he made the computations and maps for the first survey, that of Scotland. Sir Edward Thorpe's yacht was of great assistance in this part of the work, especially as regards the stations on the west coast, and among the isles. His love of the sea was also the cause of his taking part in four solar eclipse expeditions, those of 1870, 1878, 1886, and 1893. The first proved unduly exciting, for H M.S. *Psyche*, carrying the members of the expedition from Naples to Sicily, was totally wrecked.

After sixteen years at the Government Laboratory, Sir Edward returned to South Kensington as professor of general chemistry at the Imperial College of Science and Technology. He finally retired at the close of the War with the title of emeritus professor. He had been knighted in 1909, after receiving the C.B. in 1900. He was the recipient of a Royal Medal from the Royal Society, of which he was foreign secretary from 1899 to 1903, and was the first Longstaff medallist of the Chemical Society, of which he was president (after being for a number of years treasurer) from 1899 to 1901. He received honorary degrees from several

universities at home and abroad, and was an honorary member of a great number of learned societies throughout the world. He was president of the Society of Chemical Industry in 1895, and in 1921 of the British Association at its meeting in Edinburgh. This last occasion saw the beginning of his illness, for he was taken ill on arrival in Edinburgh, and was unable to deliver his presidential address on atomic structure, which was read for him by Sir Alfred Ewing.

It is only possible in the space left at my disposal to mention briefly Sir Edward's brilliant lecturing and literary ability. His early books, "Chemical Problems," "Inorganic Chemistry," "Quantitative Analysis," and "Qualitative Analysis," were used by thousands of students, while his great "Dictionary of Applied Chemistry," now appearing in a new edition, is a monumental work of the utmost importance to industrial chemistry. His biographies of Dr. Priestley and Sir Humphry Davy, the "Essays in Historical Chemistry," and his "History of Chemistry," are most readable and entertaining, as well as of scientific value, giving the personal touch which is so charming to the wonderful events in the evolution of modern chemistry. Finally, his "Yachtsman's Guide to Dutch Waterways" and "The Seine from Havre to Paris" are permanent records of a master yachtsman and valuable guides to later comers in the yachting world, whether their vessels be propelled by wind, steam, or petrol

Sir Edward Thorpe thus passes from our ken in his eightieth year, full of honours as of years, and with a published record of scientific work which it is given to few scientists to achieve He leaves no children, so that our sympathy will therefore go out in all the greater measure to his lifelong companion, Lady Thorpe, who has so devotedly watched over and cared for him, and made his home a paradise.

A E H. TUTTON

MISS L. S. GIBBS.

MISS LILIAN SUZETTE GIBBS, the news of whose death at Santa Cruz, Teneriffe, on January 30, came as a shock to her botanical friends at home, had done good work both as an investigator in the laboratory and as an explorer in many parts of the world. After a two years' course at the Swanley Horticultural College, she entered the Royal College of Science as a student in the Department of Botany under Prof. J. B. Farmer. From that time onwards her life, which might have been one of leisure, was devoted to the pursuit of science. She became a research student at the College, and the value of her work was attested by the award of the Huxley medal and the prize for research in natural science.

Miss Gibbs became early interested in the floristic side of botany, and collected in the Alps of Switzerland and Austria. In 1905 she visited South Africa with the British Association and collected in Southern Rhodesia and at the Victoria Falls. But her great contribution to floristic botany was her work on the mountain flora of various parts of the world. Between 1907 and 1915 she visited successively the mountains of Fiji, Mt. Kinabulu in British North Borneo, the Arfak Range in Dutch North-west New Guinea, the Bellenden-Ker Range in Queensland, and the mountain plateaux of Tasmania. Each of these expeditions formed the subject of a memoir—published in the Journal of the Linnean Society, the *Journal of Botany*, or the *Journal of Ecology*—in which she described her observations on the plant-formations, discussed questions of distribution of plant-life, and gave a systematic account (with the assistance of experts in some of the groups) of the very considerable collections which she brought back. A complete set of these collections is in the Department of Botany of the British Museum, where her floristic work was elaborated. She retained, however, her interest in structure and development, and her papers in the *Annals of Botany*, especially one on the development of the female strobilus in Podocarpus, based on her own collected material, are valuable contributions to this aspect of botany.

Miss Gibbs was a woman of strong personality, and keenly interested in the question of equal rights for her sex. She was one of the earliest women fellows of the Linnean Society and the Royal Microscopical Society, and was also a fellow of the Royal Geographical Society. She had many friends, who deeply regret that her work is finished, and to whom her death comes with a sense of personal loss.

THE world of geography has sustained a serious loss by the death of Mr John Bolton, which occurred after half an hour's illness on February 22. Mr. Bolton was in his eighty-third year, having been born in 1842 In 1857 he entered the service of Mr Edward Stanford, the grandfather of the present head of the firm of Edward Stanford, Limited, and although of recent years he had only acted in a consulting capacity, his connexion with the firm was continuous until his death Many leading cartographical works were produced under his direction, including the London Atlas series of maps, Stanford's 6-inch and 4-inch scale maps of London, and their series of library maps In 1884 Mr Bolton was appointed geographical expert to the Congo conference at Berlin, and in 1897 served on the Venezuela Boundary Arbitration, being loaned by the firm to the government for such service He was a life member of the Royal Geographical Society, and attended regularly the meetings of the Geographical Section of the British Association, including the visit of the Association to South Africa in 1905 He was also a fellow of the Royal Colonial Institute In the course of his career Mr. Bolton had been associated with many famous men, including General Gordon, H M. Stanley, Cecil Rhodes, Lord Kitchener, Capt. Scott, and Sir Ernest Shackleton. He possessed a personality that inspired confidence, and a geniality that endeared him to all with whom he came in contact.

WE regret to announce the following deaths.

Dr. Adolph Kemna, corresponding member of the Zoological Society of London and formerly president of the Royal Zoological and Malacological Society of Belgium and of the Belgian Society for Geology, Palæontology and Hydrology

Dr. C. Symes, president in 1897 and 1898 of the British Pharmaceutical Conference, on February 13, aged eighty-five.

Dr. A. de Watteville, for many years editor of *Brain* and distinguished for his work on the nervous system, on February 24, aged seventy eight.

Current Topics and Events.

Two subjects of philosophical and physical investigation have excited deep interest during recent years, the theory of relativity and the theory of quanta. These were discussed by Dr. J. H. Jeans in his Kelvin Lecture on "Electric Forces and Quanta," delivered on February 5 at the Institution of Electrical Engineers, and published as a special supplement to this week's issue of NATURE. The first part of the lecture deals with electric forces in the light of the theory of relativity, and it is claimed that, as all the phenomena go on as though there were no ether, the conception of an ether is superfluous If an ether does exist, it must probably be thought of as a four-dimensional structure and must be largely subjective. The generalised geometry of Einstein and Weyl can predict and explain all the systems of forces of the universe, both gravitational and electrodynamical But geometry does not explain the atomicity of electric charges or the essential difference between positive and negative electricity Again, quantum theory indicates the existence of discontinuities in Nature of a kind not contemplated in the older mechanics No one is better qualified to deal with the implications of this theory than Dr Jeans, whose report on radiation and the quantum theory published by the Physical Society of London has long been a mine of information for those interested in the subject Some of the ideas adumbrated in the final chapter of that report have now been developed further It may well be that the atomicity of the quantum theory is only another aspect of the atomicity of electric charges The quantum theory represents, perhaps, a quality of the four-dimensional continuum, which is somehow analogous to the scaliness of a crocodile skin This is equivalent to the suggestion that the "calamoids" or four-dimensional tubes of force of Prof. Whittaker should be regarded as quanta Our conception of the action of an electric field on an electron seems to require revision in the light of a recent hypothesis due to Einstein. The electric forces in Maxwell's equations serve in some way to measure the *probabilities* of jumps in the velocity and perhaps also in the position of an electron in an atom.

THE numerous statements that have been made recently by politicians and others about the great economies that could be effected by erecting very large electric generating stations are sometimes very misleading to the public. It is pointed out that, by the use of these super power stations, the cost of the coal used per unit of power generated would be halved. It is generally concluded, therefore, that the cost of power to the consumer would be reduced by a half When we remember, however, that only from 20 to 25 per cent. of the total cost of generating a unit is due to the coal used, it will be seen that the reduction of price to the ultimate consumer would only be about 12 per cent, and not the 50 per cent. which the public have been led to expect. Similar conclusions apply to water power. We have received from the Smithsonian Institution of Washington an excellent report, by S. S. Wyer, on the power possibilities and preservation of Niagara Falls. It is pointed out that the erection of the requisite hydro-electric plant is less than half that of the total scheme. Few realise that about 80 per cent. of the cost of delivering the energy to the resident consumer is incurred after the power has left the generating station The money used for carrying out an enterprise, whether state-owned or not, must ultimately come from individual owners, and they have an obvious right to receive a hire or rental for it. An interesting comparison is made between the systems adopted on the Canadian and on the American side of the Falls. In Canada the Government owns about 79 per cent of the hydro-electric system. The service in Ontario is not taxed, so that the lowering of the cost to the consumer is done at the expense of the tax-payers of the districts in which the property is located. On the American side, about 10 per cent. of the price of the service has to be paid for taxes. The rate of recession of the crestline of the Canadian Falls, which carry 94 per cent. of the water, is about 5 feet per annum. On the American side it is only about 2 inches per annum. Methods of preserving the scenic beauty of the Canadian Falls and preventing them from "gradually committing suicide" are discussed.

A STEP, which may eventually be one of far-reaching importance, has recently been taken by the authorities of the London School of Hygiene and Tropical Medicine. They have appointed a Rhodesian Research Fellow in the person of Dr. G. R. Ross, at present lecturer in the University of Leeds and a former graduate of the University of St. Andrews. This development is the direct outcome of the co-operation which existed between the Government of Southern Rhodesia and the old London School of Tropical Medicine whereby, on two occasions, Dr. J. G. Thomson, Director of Protozoology at the School, visited Southern Rhodesia and carried out research work in connexion with blackwater fever. The results of Dr. Thomson's useful inquiries have appeared in the form of a well-illustrated monograph, a pioneer publication. Dr. Andrew Fleming, the Medical Director, Southern Rhodesia, felt, however, that this was merely a beginning and that the question of blackwater fever, and indeed of other tropical maladies, was so important from the point of view of the white settlers and of the general development, not only of Southern Rhodesia but also of the whole chain of Central African tablelands, that measures should be taken to ensure a continuance of such research work. He found his Government in a sympathetic mood and, together with Sir Francis Newton, the High Commissioner of Southern Rhodesia, he approached the Board of Management of the London School of Hygiene and Tropical Medicine after some preliminary discussions with the Director of the School. Eventually it was arranged that, for a period of three years, the Southern Rhodesian Government, in addition to making an annual grant

towards the expenses of the Field Station, would undertake to provide laboratory accommodation and equipment together with travelling expenses in Rhodesia for one or more research workers to be appointed and sent out by the London School. In accordance with this arrangement, Dr. Ross, accompanied by a trained laboratory assistant, will leave England in March.

SIR OLIVER LODGE's fifth broadcast talk from the London Broadcasting Station 2 LO on "Ether and Reality" was delivered on Tuesday, March 3. His subject was "Electromagnetism. How Radiation is Generated." An electron at rest has nothing magnetic about it; but the path of a moving electron is surrounded by magnetic lines of force, as an umbrella might be surrounded by indiarubber rings When the electron is suddenly stopped, these rings are "shocked" off, spreading out as a pulse or shell of radiation with the speed of light, carrying away the energy and momentum. A moving electron has additional mass when stopped, this mass disappears as a quantum of radiation; the size of the quantum depending on the previous speed. There are strange unexplained facts looming ahead of us Sometimes, Sir Oliver said, we feel as if radiation were a half-way stage between ether and matter. Matter is discontinuous. Is light discontinuous? Is light a kind of matter which is bound to travel at a fixed speed, unless perchance it be modified into an electron? The difficulty and the interest of the problems before us are only equalled by the ingenuity with which they are being attacked. The eternity of the cosmos seemed at one time in doubt by reason of the dissipation of energy. now there is some glimpse of a way out. Matter tends to fall together gravitationally, but radiation tends to spread to the confines of the universe, and however diluted it retains its vigour What becomes of the quanta? Why is no speed greater than that of light possible? Some revelation is dawning upon us, and confronted with a majestic vision of reality, we—like those other explorers on their first view of the Pacific Ocean—have

"Look'd at each other with a wild surmise—
Silent, upon a peak in Darien."

SIR JAMES C. IRVINE in his discourse on Friday evening, February 27, at the Royal Institution, dealt with sugars from the point of view of the organic chemist. Within the last fifty years many new sugars have been isolated from natural sources; others, unknown in Nature, have been prepared synthetically; formulæ have been ascribed to them, and in many cases the structure has been determined. In order to make further progress, a new phase must be entered upon when only such reactions of the sugars will be studied as proceed under conditions approaching closely to those which obtain in the living tissues; conditions which will not admit of the use of solvents or reagents inimical to life, and in which the optical, electrical and thermal factors will be rigidly controlled. Above all, new types of synthesis are required, and only when the chemist resolves to regard it as a crime to conduct a sugar-reaction at the boiling point is there any real hope for sugar chemistry. Eighty years ago Faraday was investigating the electrical properties of cane-sugar, and the recollection inspires the hope that the research now associated with the Royal Institution may again be applied to the whole series of carbohydrates. What a prospect is opened up when a well-founded conception of constitutions based on both physical and chemical evidence shall have been acquired.

AT the forty-seventh annual general meeting of the Institute of Chemistry held on March 2, the president, Prof. G. G. Henderson, after referring to the loss sustained by British chemistry by the death of Sir George Beilby, one of the past presidents, announced that the Council had invited the co-operation of the Society of Chemical Industry and the Institute of Metals, of which Sir George had also been president, in establishing some fitting memorial in his honour. The Institute was frequently invited to appoint delegates to participate in public inquiries Such invitations were welcomed, but the Council had felt obliged to give expression to a mild protest that provision could not be made to lighten the sacrifice of time and expense which the duties of such representatives entail. The Council was diffident about asking fellows who were resident in the country to attend Government committees at their own cost and without emolument. The attitude of authorities towards scientific men had been reflected in the speeches of Ministers of the late Government, who apparently regarded the professional scientific man in the civil service as a very useful person in an ancillary or subordinate position, but it should be insisted upon that scientific departments should be controlled by competent scientific men. Chemists who were also capable men of affairs were available, many such held high positions in industry, and they were coming more and more into positions of control. It was the business of the Institute to ensure the supply of such chemists for the benefit of the country The following officers for the year ending March 1926 were elected *President*, Prof G G. Henderson; *Vice-Presidents*, Prof. E. C. C Baly, Mr E R Bolton, Mr. A. Chaston Chapman, Dr T Slater Price, Prof. A. Smithells, Mr. E W. Voelcker, *Hon. Treasurer*, Mr. P. H Kirkaldy. At the conclusion of the formal business, the president, supported by Prof Thomson, made a presentation, on behalf of the fellows and associates, to Mr. Richard B. Pilcher on completing thirty years as secretary and twenty-five years as registrar and secretary of the Institute. In the evening the Council entertained Mr. and Mrs. Pilcher and their family to dinner at the Hotel Russell, followed by a reception.

ON February 28, at 9.23 P M., a strong earthquake was felt in the eastern United States and Canada. The first accounts do not suggest a shock of unusual or destructive intensity, but it is possible that its importance was not fully realised at the time the messages were sent. Two facts in the brief reports seem to indicate the severity of the earthquake. One is its great duration, even supposing that the estimate

of four minutes at New York was much exaggerated The other is the magnitude of the disturbed area. An earthquake that was noticeably felt in New York, Richmond (Virginia), Louisville (Kentucky), Chicago, and Montreal must have disturbed a district at least 750 miles in diameter and containing not less than 450,000 square miles, that is to say, an area greater than that affected by the San Francisco earthquake of 1906 At New York the movement was strong enough to break the writing pointer of the seismograph at Fordham University. It was recorded at West Bromwich and, no doubt, at many other places in Europe

AN important conference upon applied microscopy is to be held in Sheffield on April 20 next and following days under the auspices of the Royal Microscopical Society at the invitation of the University of Sheffield, the civic authorities, the Master Cutler, and the loca technical colleges and research associations A local committee has been appointed representative of the academic and industrial research interests, and the programme includes a large number of communications and discussions dealing with technical problems connected with iron and steel, wood, coal, paper, textiles, industrial diseases, and microscopical optics Visits to works and laboratories are being arranged, and an imposing exhibition of instruments and apparatus will be open throughout the meeting. It is also hoped to arrange with the railway companies to grant cheap travelling facilities to those attending the conference The conference is open to all interested in technical microscopy, and full particulars can be obtained from the Secretary, Royal Microscopical Society, 20 Hanover Square, London, W.1, or from the Local Secretary, Mr E J. Thackeray, Dept. of Applied Science, University of Sheffield.

THE fifth International Congress of the History of Medicine will be held at Geneva on July 20-25, with Dr Charles Greene Cumston as president and Sir D'Arcy Power as president of honour The following papers among others will be read medical operations in the stone age, by M. Eugène Pittard of the University of Geneva, Albert von Haller and the "Disputationes chirurgicae selectae," by Sir D'Arcy Power, Robert Whytt, an eighteenth-century neurologist, by Dr John D. Comrie, the history of typhoid fever in the child, by Prof. P Gautier, a letter of Tronchin and the Suttonian method of inoculation, by Dr J G. de Lint, Voltaire and medicine, by Dr. J D Rolleston, goitre at Geneva in the Middle Ages, by Dr E. Wickersheimer, Lavater and his successors, by M Fosseyeux, a note on the history of diagnosis in medicine, by Dr. F. G Crookshank, a letter of Girolamo Fracastoro on poetry, by Dr. J. W. S. Johnsson of Copenhagen, historical researches on the history of anatomy in the Ateneo Romano, by Dr. P. Capparoni, medical literature of the seventeenth century as exemplified in the Elzevir Press, by Dr. E B Krumbhaar, hygiene and public health in the early civilisations, by Mr C J. S Thompson; the origin of veterinary art, by Sir Frederick Smith; the history of magic in the cure of disease, by Prof. Jeanselme; Martin Luther and his noises in the ear, by Prof. G. Bilancioni; a medical congress at Rome in 1681–82, by Dr. C. G. Cumston; and Benjamin Waterhouse, an American pioneer, by Dr J. W. Courtney. Further information can be obtained from the general secretary of the Congress, Dr. A. de Peyer, 20 Rue Général Dufour, Geneva.

THE new journal entitled *The Industrial Chemist and Chemical Manufacturer* constitutes a somewhat novel departure in the sphere of chemical journalism, because it will be the only monthly publication of its kind in Great Britain, and because it is very attractlively got up The general style resembles that of some American journals which contain articles profusely illustrated and advertisements very effectively displayed. It is interesting to note that in the new publication the advertisements of many old-established firms that have, apparently, never been radically changed within living memory, appear in an entirely new dress—the designs and the letterpress being entirely novel In the journal proper the main feature is the large number of articles, many of which are written by well-known authorities. Among the subjects treated are vanadium, saccharin, power alcohol, petroleum refining, glass, disintegrating mills, lime, vegetable adhesives, disinfectants, and adhesives. The manner of treatment may be described as not severely technical, the object being to attract and interest not only the chemist, but also those employed in or associated with chemical undertakings, including the works' manager and the directorate, who may have no expert knowledge of chemistry. This is a field which has hitherto been neglected or inadequately cultivated, and in extending a welcome to the new publication we express the hope that it will be particularly successful in fulfilling this part of its programme.

ON Tuesday, March 10, at a quarter past five, Prof. E. N da C. Andrade will begin a course of two lectures at the Royal Institution on the evolution of the scientific instrument, and on Thursday, March 12, Dr. Leonard Hill will deliver the first of two lectures on the biological action of light. The Friday evening discourse on March 13 will be delivered by Prof. Gilbert Murray, on the beginnings of the science of language, and on March 20 by Prof. J. W. McBain, on soaps and the theory of colloids.

APPLICATIONS are invited by the Board of Management of the Christie Hospital, Manchester, for the post of cancer research worker, whose duties will be to carry out research work on the blood in cancer. Candidates should have a medical qualification and experience in clinical, pathological, and biochemical methods. The latest date for the receipt of applications, which should be sent to Dr C. Powell White, Christie Hospital, Manchester, is March 13.

AT the annual general meeting of the Physical Society held on February 13, the following officers were elected. *President*, Mr. F. E. Smith; *Vice-Presidents (who have filled the office of President)*, Sir Oliver J. Lodge, Sir Richard Glazebrook, Dr. C

Chree, Prof. H. L. Callendar, Sir Arthur Schuster, Sir J. J. Thomson, Prof. C. Vernon Boys, Prof. C. H. Lees, Sir W. H. Bragg, Dr. Alexander Russell, *Vice-Presidents*, Dr. E. H. Rayner, Dr. J. H. Vincent, Dr. D. Owen, Mr. C. R Darling; *Secretaries*, Prof. A. O. Rankine, Imperial College of Science and Technology; Mr. J. Guild, National Physical Laboratory, Teddington, Middlesex, *Foreign Secretary*, Sir Arthur Schuster, *Treasurer*, Mr. R. S. Whipple, *Librarian*, Mr J. H. Brinkworth.

THE series of Early Chellean hand-axes found during 1924 by Mr. Reid Moir upon the foreshore, and in a deposit representing the base of the Cromer Forest Bed, at East Runton and elsewhere on the Norfolk coast, is now being exhibited in the Museum at Ipswich, and the specimens can be examined by any one desirous of doing so The early flint implements of East Anglia are now arranged in the following sequence, which illustrates the succession of human cultures in Late Pliocene and Early Pleistocene times, namely, (*a*) specimens of Harrisonian eolithic type, (*b*) pre-Chellean forms from beneath the Red Crag, (*c*) Early Chellean hand-axes from the base of the Cromer Forest Bed, and (*d*) Chellean, Acheulean, and Mousterian implements from various deposits in Suffolk and Norfolk

THE Soviet Government of Russia has taken steps to protect the *zubr* or European bison, and incidentally other rare forms of life, in the Western Caucasus, by declaring an area of about 250,000 dessiatins, or approximately 625,000 acres, a reserved area under the control of a special official with the title of *zubrovni zapoviednik*. Within this area " all activities damaging the natural relief of the surface, such as the felling of timber, pasturing of cattle, opening of quarries, etc.," are forbidden.

THE Cambridge Instrument Co., Ltd, have issued a new list, No 194B, dealing with thermoelectric pyrometers. The catalogue deals in succession with general principles, indicators, recorders, thermocouples, cold junction control, and pyrometer tester. The latter is a compact form of potentiometer suitable for checking the accuracy of any type of thermoelectric potentiometer. An interesting item is the new thread recorder, which is enclosed within a robust moisture and fume-proof metal case instead of the customary teak cabinet Recorders of this type are supplied making up to six records on one chart. These may include records of temperature, carbon dioxide percentage, and carbon monoxide percentage It might be remarked that the carbon monoxide indicating apparatus is a development of the carbon dioxide type The amount of carbon monoxide is obtained by a differential measurement of the carbon dioxide present before and after the flue gases are passed through a small electric furnace containing copper oxide which converts any carbon monoxide present into carbon dioxide

ERRATUM.—The words " on the Use of Preservatives and Colouring Matters in Food " appearing on p. 222, col. 2, of the issue of February 14, in the concluding sentence of the review entitled " The Chemistry of Flour Milling," were inserted in error after the author had passed his proof The Report of the Departmental Committee already published makes no reference to the bleaching and improving of flour, but a further report will appear in due course.

Our Astronomical Column.

THE DISTANCE OF THE ANDROMEDA NEBULA.—There have been several very discordant estimates of the distance of this object. A new one has now been made by Prof. Hubble, and is briefly described in *Popular Astronomy* for February. He has found several Cepheid variables in the nebula, determined their periods, and deduced their absolute magnitudes in accordance with Prof. Shapley's formula The resulting distance of the nebula is 950,000 light years, a distance which would make it of the same general order of size as our galaxy.

This is probably a more trustworthy estimate than those previously made; a possible correction might arise from absorption of some of the stars' light in traversing the nebulous matter.

A note in *Popular Astronomy* points out that the 7th magnitude Nova that appeared in the nebula in 1885 would at this distance have been 140 million times as bright as the sun.

ANNUAIRE DU BUREAU DES LONGITUDES, 1925.—This little handbook is now very well known, and contains as usual, a large amount of useful information —astronomical, meteorological, physical, geographical, political, etc

The special essays this year are by M. E. Fichot on the effect of the earth's rotation on the tides, and by M. G. Ferrié on the use of lamp valves in wireless telegraphy and telephony, with applications to astronomy. A little more care would seem to be called for in editing the astronomical tables: p. 289 gives the revolution of Mercury 2 days too great, a very serious mistake, p 302 in giving the elements of Neptune's satellite omits to notice the very interesting variation in its orbit plane

The information about the comets of 1923 is not up-to-date, much better elements of comet 1923 *a* were available months ago The object described here as comet 1923 *b* was found to be a minor planet more than a year ago. there are, moreover, three misprints of proper names in the account of it, " Harward," " Seegrave," " Crowford ", p 310 gives the erroneous period 12·1 years (more than a year too short) to Tuttle's comet This mistake has been repeated for several years and has misled many people. This period was deduced from a short arc, and was not intended to be taken as accurate

UNION OBSERVATORY, CIRCULAR 62.—This circular, dated last June, contains a number of important observations, which include the transit of Mercury (third contact 24 seconds before Nautical Almanac, fourth contact 35 seconds before), also long series of observations of Reid's Comet 1924*a* and Eros, which were too far south for European observers; also 114 occultations of stars by the moon, observed in 1923, which are fully discussed. There are reproductions of the spectra of Nova Aquilæ on 21 days, June 11–August 10, 1918, which are conveniently arranged for studying changes The identity of the Nova with a 10th magnitude star in the Algiers astrographic catalogue was independently detected by the blink microscope at Johannesburg.

Research Items.

PREHISTORIC POTTERY IN PERU.—Messrs A. L Kroeber and D. D. Strong, in a study of the pottery from Ica collected by Dr. Max Uhle for the University of California some years ago, pay a well-deserved tribute to the valuable but too little recognised work of this archæologist in South American, and especially Peruvian, archæology In the case of the pottery from Ica now described in University of California Publications in American Archæology and Ethnology, vol 21, No 3, and in the case of the pottery from Chincha, of which an account by the same authors appeared in a previous issue, they find that their independent study completely corroborates Dr. Uhle's suggested classification and sequence in all important respects The pottery from graves in the Ica Valley, which lies on the coast of southern Peru, is classified into seven periods, as against the three at Chincha, representing more or less successive culture phases—Inca, late Ica II. and I (corresponding closely with the three phases at Chincha), Middle Ica II. and I, Early Ica or Epigonal, and Nazca or Proto Nazca The last named is unique and distinctive in colour, design, and shape The stylistic development from Middle Ica I to Inca is so continuous that when once Inca is accepted as latest, any other sequence is impossible The Ica Epigonal and Middle Ica are undoubtedly related to Tiahuanaco style, but it is difficult to see that Epigonal represents a decadence of Tiahuanaco styles as Uhle supposes

THE THEORY OF SENSE DATA.—In a lecture published in the Journal of the Royal Astronomical Society of Canada, Dr H H Plaskett expounds what he calls the descriptive view of science This is the view that the objective content of science consists exclusively of the data of sense, that these sense data are not subjective aspects of reality but the actual non-mental content of the scientific object itself which is a construct of them, that the metaphysical concepts of substance and cause have no place in science, which can quite well dispense with them, that the atoms and molecules of physics and chemistry are not real existents but concepts Dr Plaskett seems to have taken this view from the chapter on sense data in Hobson's Gifford Lectures and to find support for it in Pearson's "Grammar of Science" The first of these does not profess to be original, but gives an excellent account of the recent controversy aroused in philosophical circles by the new realism of Mr. Bertrand Russell and Dr. Broad If Dr Plaskett had gone directly to the origin of this theory in modern times, Mach's "Theory of Sensations," he would probably have been aware of some difficulties of his descriptive view of science which are unnoticed in his lecture. Mach found, in fact, that, try as he would, he could not get scientific objects out of sense data, they are not implicit in them, and yet only as sense data do scientific objects exist for us at all Mach spurned metaphysics, and he put forward as the only alternative to a scepticism like Hume's a theory of psycho-physical parallelism. This for him was the only possible way of objectifying scientific knowledge The ideal of a science of pure description, renouncing all explanation, is no new thing It goes back at least to Bacon, but it has never proved satisfying to the restless spirit of scientific inquiry. Since Berkeley, the problem of perception has made it still more disconcerting. It is well, however, that we should be continually reminded of the initial difficulties, even the paradoxes, which surround the problem of the true method of scientific procedure.

CUTTING SEED POTATOES.—Potato growers frequently hesitate to cut their seed potatoes on account of the uncertainty as to the yield per plant and to the growth and healthy development of the cut sets This second point has been investigated by J. H. Priestley and G. C. Johnson (Journ. Min. Agric 31, No 11), who indicate the precautions needed to eliminate this uncertainty. The healing of the cut surface of a tuber is brought about by the deposition of a suberin deposit, which forms a barrier to the entry of moulds and bacteria capable of attacking and rotting the tuber. If the potato is cut in moist air this suberin layer is continuous over the whole surface, but if the air be dry the suberin is patchy and organisms are able to penetrate through the cracks between the patches, thus damaging the tuber Field trials have proved the importance of this fact. Similar tubers of Great Scott were cut and exposed to sun and air for 24 to 48 hours, or kept in a damp, warm place for the same time. Much heavier crops were obtained with the latter treatment, 15½ tons against 6½ tons, 23½ tons against 14½ tons, etc, similar results being obtained with other varieties in other districts Apart from the question of yield, it appears that the certainty of growth from cut sets is much greater if precautions are taken to protect the sets from sun and wind after cutting before they are planted.

OBSERVATIONS ON HOOKWORM LARVÆ.—Dr L Fabian Hirst describes (*Ceylon Journ. Sci*, Section D, Medical Science, vol 1. pp 1-26, 1924) investigations on the epidemiology of hookworm disease in Colombo His attention was directed to the problem in consequence of a severe outbreak of hookworm dermatitis and disease amongst coolies handling soil from certain trenches in a field used for the disposal of septic tank sludge The larvæ of Ancylostoma, Necator, and Strongyloides exhibit aerotropism, *i e* they attach themselves by one end to some fragment of fibre or similar substance on the surface of the soil and extend the rest of their bodies into the air, constantly moving as if in search of some additional support The movement of Strongyloides larvæ is more jerky and gyratory; the hookworm larvæ exhibit a slow undulating motion. The author figures an apparatus in which buckskin leather is employed as a means of bringing about a separation between penetrative larvæ (which pass through the buckskin into a warm solution on the other side) and others present in the soil The species of the penetrative larvæ (Ancylostoma and Necator) can be definitely determined only after development to the sexually mature form in the intestine of a suitable host In laboratory experiments the author found that larvæ of *Necator americanus* could be recovered from the surface of infected soil for at least 108 and up to 124 days Larvæ lived about three months in water and fluid extracts of trench soil; they died much more rapidly in soils and fluids kept at blood heat than in the same media at room temperature.

GROWTH IN INDIAN MOLLUSCS.—In an account (Records, Indian Mus., vol. xxvi. pp 529-548, Nov. 1924) of his observations on growth in Indian molluscs, Major R. B. Seymour Sewell deals with five freshwater species and four marine brackish-water species—all gastropods except one (*Mytilus variabilis*) He examined 212 examples of *Pyrazus palustris*, which occurs in abundance in Nankauri Harbour, Nicobar Islands, in a swamp which is submerged at high water, and found that correlated with the gradual increase

in size is a remarkable change in the character of the radula. So marked is the difference between the radulæ of the smallest and the largest specimens that one might reasonably doubt whether they belong to the same species In the smallest individuals, having a height of about 12 mm., the radula consists of rows of teeth—seven in a row (dental formula 2 1.1 1.2), each tooth possessing several cusps. As growth proceeds the cusps on the teeth become gradually reduced in number until finally the central tooth presents only a single median cusp, the lateral tooth has a single cusp and a trace of a second one, and the two marginal teeth have a single cusp with traces of one or two small ones. The reduction seems to be brought about by a process of fusion rather than by suppression, and, so far as can be ascertained, is not correlated with any change in the habits of the mollusc. No corresponding change occurs in the other gastropods examined

BLACK SHEEP.—Wensleydale sheep have white wool, but the skin of the face and ears is deep blue, and this colour may extend to other parts of the skin Breeders select for a maximum amount of pigment. The breed produces about 15 per cent. of black lambs, together with a number which are "pale blue" and very occasionally one which is pure white Mr F W Dry, from breeding experiments (*Journ Genet.*, vol 14, No 2), concludes that the black is a simple recessive, since blacks bred together give only black offspring The same is true of blacks in certain other breeds of sheep The blue-faced sheep are found to be heterozygotes analogous to the Blue Andalusian fowl, in other words, a black sheep with a (dominant) white coat On the other hand, the Karakul sheep is a dominant black When crossed with white breeds, the lambs are pure black Such F_1 hybrids are now widely bred and their fleeces used as fur, but in the adult the colour becomes grey or dirty white In black Welsh mountain sheep the colour of the coat and horns is also apparently dominant in crosses Mr. J. A. Fraser Roberts (*Journ Genet.*, vol 14, No 3) describes experiments with this breed A pattern known as "badger-face" also occurs, which is white with black markings on the face, belly, and legs This appears to be recessive to both black and white In crosses between black and badger-face a white lamb has been known to appear Such cases of "reversed dominance" have been recorded in other breeds. Their further investigation is a matter of much genetical interest. The badger-face marking has also been studied by Wriedt in a Norwegian breed of sheep. Individuals with reversed badger-face markings, *i.e.* black where white should appear and vice versa, are also known to occur

NEW PLANT ILLUSTRATIONS.—Two numbers of *Curtis's Botanical Magazine* have recently appeared under the energetic editorship of Dr. Stapf, being parts i. and ii. of vol. 150, each containing plates of eleven plants, and each including one rhododendron and one primula, *R. bracteatum* and *P. Bulleyana*, in part i., *R. glischrum* and *P. melanops* in part ii. Other interesting plants in part i. include *Stellera Chamæiasme*, an example of a small genus of Thymelaceæ that has not previously figured in the *Botanical Magazine*; *Lindmania penduliflora*, a Peruvian example of this genus of Bromeliaceæ which may be in Nature an epiphyte like so many of the family, although the immediate allies of this plant grow on the ground on the edge of the forest; and a species of the cactus-like genus of the Senecioneæ, *Kleinia stapeliiformis*. Part ii. includes some very striking plants, notably an epiphytic member of the Vacciniaceæ *Agapetes speciosa*, with brilliant scarlet flowers; a species of an Orobanchaceous genus, *Æginetia indica*, successfully raised at Kew as a parasite upon the roots of the sugar cane, which will apparently only grow upon the roots of monocotyledons, and a shrub from Natal, *Ochna serrulata*, with yellow flowers and very striking fruits, in which the blue-black drupelets stand out against a vivid background of vermilion-coloured, enlarged sepals.

FOSSIL CRANE FLIES FROM SOUTH AMERICA.—Two species of crane flies have been discovered by G R Wieland (*Amer. Journ Sci.*, 9, Jan 1925, p 21) in the Rhætic beds of Minas de Petroleo, south-west of Mendoza, Argentina. The larger (*Tipuloidea rhætica*) had a wing spread of 2·6 inches, so that it rivalled in size the Australian "robber fly." The smaller form (*Tipulidites affinis*) had a wing spread of half an inch. This discovery emphasises the great antiquity of the Diptera

UINTACRINUS IN THE CHALK OF WESTERN AUSTRALIA.—Remains of the free-swimming crinoid, Uintacrinus, have been found in the chalk of Gingin, Western Australia (T H. Withers, Journ Roy Soc. W. Australia, 11, 1924, p 15) This discovery gives important evidence of the age of the Gingin Chalk, since Uintacrinus is characteristic of the lower part of the Marsupites zone of the Upper Chalk. It also shows that this crinoid, hitherto known from Utah, Kansas, England, and Westphalia, had a very wide geographical distribution

THE DOLDRUMS OF THE NORTH ATLANTIC.—The *Marine Observer* for February contains an article on "The Doldrums of the North Atlantic" by Mr C S Durst The author gives credit to Maury and Toynbee for their full discussion of this interesting region Toynbee's discussion was carried out with the perfection of minuteness, comprised by elaborate charts and voluminous letterpress It has the advantage of being based chiefly on the results from sailing ships, the observations being gathered by the Meteorological Office. An attempt has been made at a further discussion which may be of scientific value, but with the present-day steam vessels the region for the sailor has lost much of its "torment" Fig 3 (p 21), to which the author attaches considerable importance, is at least for the first ten days open to considerable doubt so far as the northern and southern boundaries of doldrum in March 1923 are concerned, and the resulting width of doldrum certainly is not 600 miles as given in the text

ICE IN THE BALTIC SEA.—Among a number of interesting publications on various aspects of Baltic meteorology and oceanography published by the Havsforsknings Institutet of Helsingfors a particularly detailed paper deals with the occurrence and distribution of sea-ice during the winter of 1920–21 (No 22, Isarna Vintern, 1920–21) The observations, which were gathered at coast stations and Finnish lightships, are given in full and entered on a series of coloured maps for the Gulf of Bothnia, the Gulf of Finland, and the Finnish water of Lake Ladoga. These charts show the beginning of the ice in the north of the Gulf of Bothnia in early December and its gradual extension southward. In the year under review the waters of the Aland Archipelago were not blocked until late January, but soon after that date fast ice extended across to the Abo Archipelago and the coast of Finland and remained until early March. The period of greatest extension of ice in the Gulf of Finland was the middle to the end of February, when, as usual, the Gulf was more or less entirely blocked In early April the southern coasts of Finland were clear, while the western coasts cleared between the beginning of April and the middle of May. These dates appear to have been earlier than usual. This

and other publications of the Institute are in Swedish, with very brief German summaries.

SPARK IGNITION.—A knowledge of the conditions under which an electric spark in an explosive mixture of gases will initiate an explosion is of great importance in the mining, motor, and other industries, but the results of experiments made hitherto have been inconclusive. In a communication to the *Philosophical Magazine*, which appears in the February issue, Mr. J. D. Morgan gives an account of his experiments on the igniting powers of inductance sparks in direct and alternating current circuits, and comes to the conclusion that the thermal theory of ignition is sufficient to cover all the known facts. According to this theory, it is necessary to raise a sufficient volume of the gas in the immediate neighbourhood of the spark to a sufficiently high temperature before ignition results, and if both conditions are not satisfied the flame produced in the gas immediately in contact with the spark will not spread. To satisfy them a certain minimum energy must be imparted to the gas in a fixed short time, and this is in general more easily done by a capacitance than by an inductance spark, but there is no difference between the effects of the latter when in direct or in alternating circuits. The cooling effect of the electrodes is very marked and must be taken into account.

TESTING PHOTOGRAPHIC PLATES.—The February number of the Journal of the Royal Photographic Society is devoted to the first session of the Conference on the Standardisation of Plate-testing Methods which was held at the Society's house on December 9. The papers read and the discussions on them are given in full. The subjects treated of at this meeting were (1) the light source, primary and secondary, (2) the exposure mechanism, (3) the development. The first paper is from the National Physical Laboratory and deals with standards of light. Of the standards at present available for sensitometry either the crater of the carbon arc or a gas-filled tungsten lamp, operating at a colour temperature of 2950° absolute, is recommended, but in either case definite specifications of details would have to be prepared. Dr. Helmuth Naumann gives a formula for a colour filter in gelatine which contains six different dyes, and changes the light from a vacuum tungsten filament lamp into "daylight" from about 3000 Å.U. to about 7000 Å.U. with sufficient accuracy for most photographic purposes. It seems generally acknowledged that the intermittency error caused by rapidly revolving sector wheels placed in the path of the light should be eliminated. With regard to development, it is argued on one hand that this should be uniform, and, on the other hand, that uniformity would not be fair, because different plates need different treatments to get the best results of which they are capable. In all, ten papers were read and discussed.

THE γ-RAY SPECTRA BY THE CRYSTAL METHOD.—M. J. Thibaud has recently described experiments, in which the frequencies of monochromatic γ-rays are arrived at by converting the radiations into β-spectra, by means of the photoelectric effect on different elements, and measuring the energies of the electronic streams emitted. In the *Comptes rendus, Acad. Sci. Paris*, of January 12, he describes how, using de Broglie's method, with a rotating crystal of rocksalt and photographic registration, he has been able to make measurements with angles α of reflection scarcely more than a fraction of a degree. The velocity of rotation was less than 1° in twenty-four hours. Glass tubes containing 40 mgm. of radium bromide in equilibrium with its products were employed, and also a preparation of mesothorium. The spectra consist of clear sharp lines, with no continuous bands, and the following values have been found for radiothorium or mesothorium.

No.	Int.	λ in Å.	Energy in volts.	Origin.
1	strong	0·168	73,500	—
2	"	0·145	85,000	Rd Th
3	weak	0·062	198,000	"
4	medium	0·052	236,000	Th B

The indirect method gives 233,000 for the energy in volts of a γ-ray from thorium-B, which agrees with No. 4 above within the limits of probable error; this line has been found by Meitner and by Ellis. Fräulein Meitner assumes a γ-ray 0·146 Å. to explain the β-radiation of radiothorium, which agrees with No. 2. The origin of No. 1 is not explained. Rays with energies of 273 and 298 kilovolts found by the indirect method, but weaker than the 233 kilovolt ray, have not as yet been observed directly. The spectrum obtained with radium confirms the two lines found by Rutherford with α about 1° 30′.

TYPOGRAPHIC INKS.—The technology of printing inks is described by Dr. N. F. Budgen in the *Chemical Trade Journal* for January 23. Typographic inks (used for book-printing, labels, etc.) are softer and thinner than lithographic inks, which must be unaffected by water. The essential constituents of printing inks, apart from the pigment, are the oil (usually linseed, though soya-bean, perilla, and other oils are often used), and the varnish (largely made from rosin oil). Cheap inks contain varnish made from mineral oils. The pigments used for obtaining different coloured inks and the incorporation of the ingredients are described in detail. Cheap black inks contain carbon black. More expensive inks use a black made from rosin oil.

SUGAR INDUSTRY IN GREAT BRITAIN.—The English beet-sugar industry is described in an article in the *Chemical Trade Journal* for January 23. The first factory to be erected in England was put up near Maldon (Essex) about 1832. It did not continue long, and the next factory, erected at Mount Mellick, Queen's County, Ireland, in 1851, also closed down at an early date. A works put up at Lavenham, Suffolk, in 1868, closed down ten years later; it was recommenced in 1885, but only worked for a few weeks. The primary cause of these initial failures seems to have been lack of beet, which the farmers would not produce in sufficient quantities. The more recent schemes are mentioned. The Cantley factory (near Norwich) was opened in 1912; it was closed during the years 1914–1920, but since the latter date it has operated each season. The old and modern methods of refining beet-sugar are described; the modern bone charcoal filtration method does not appear to be used in England. Some possible developments in the sugar industry are described in *Chemistry and Industry* for January 23. The article is mainly concerned with the use of vegetable charcoal for refining purposes; it is more economical than bone charcoal. One such charcoal is "suchar"; whereas a factory turning out 200 tons of raw sugar daily requires about 600 tons of bone black for refining purposes, the same factory would require only about 30 tons of "suchar." It is claimed that this reduces the cost of refining by one half. The "suchar," after it has been used twice, is washed and revivified by passing an electric current through it. This burns off the impurities without impairing the activity of the carbon itself. Glucose can now be obtained in a colourless crystalline form on a large scale; it is marketed as "ceralose." Crystalline fructose has also been obtained on a laboratory scale under conditions which make the transference of the method to the manufacturing scale almost certain of success.

Physiological Standardisation.

THE use of substances in the treatment of disease has, probably in a majority of cases, been empirical for some time after their discovery and adoption; in fact, in spite of recent advances in chemistry, through which the actual structure of many drugs has been elucidated, pharmacology is in many instances only able to describe the actions of drugs on living tissues without at present finding it possible to give the actual reasons for these actions The problem is part of the wider one of the relation between chemical structure and physiological action. In those cases where the chemical structure is known, it is easy to investigate the action of known quantities of the drug upon a number of organisms of the same or different species and thus arrive at the minimum dose which is effective, and at the maximum dose which is safe, for no drug is absolutely harmless when the dose has exceeded a certain specific limit. But when a substance cannot be isolated in a pure state and its chemical structure is unknown, as is the case for example with the active principles obtained by extracting certain glandular organs, the sole indication of their presence being the effects they produce upon living tissues, it is essential, to get comparable results with different samples and to protect the patient against a possible overdose, to have an approximate idea of the strength of the sample in terms of its physiological action. It is a common experience to find that extracts prepared in the same manner and containing a known amount by weight of the original organ, may yet differ enormously in physiological activity This variability is due to variations in the condition of the gland before extraction and to varying loss of the active principle during this process

To illustrate the methods used in physiological standardisation, those employed in assaying the active principle or hormone of the posterior lobe of the pituitary gland, commonly known as pituitrin, and that obtained from the pancreas, called insulin, may be described briefly, with special reference to recent work on the subject.

Pituitrin acts as a stimulant to smooth muscle, affecting the muscle fibres directly, its main effect on intravenous injection is to raise the blood-pressure, but after administration per os, or intramuscularly, its absorption is too slow to produce this effect, and yet it will cause contraction of the uterus, an organ the contractile power of which is due to the smooth muscle in its wall. In clinical medicine it is used chiefly for the latter purpose in the later stages of labour Methods of assay have been based on its effects on the blood-pressure and on the uterus Dale and Burn (Medical Research Council Report, No. 69) have given a detailed account of the latter: the uterus of the virgin guinea-pig is used as the test object, and an extract of the posterior lobe of the pituitary, prepared in a certain manner, as the standard It would be convenient to use as standard a substance of known composition which could be obtained in a pure condition, having the same stimulant action on smooth muscle as pituitrin. Unfortunately, tests with histamine and potassium chloride showed that uteri varied in sensitivity to these substances and to pituitrin independently.

Hogben, Schlapp, and Macdonald (*Quart. J. Exp. Physiol.*, 1924, vol. 14, p. 301) have recently described a method of assay based on the rise of blood-pressure produced by intravenous injection. It is not yet certain that the principles producing rise of blood-pressure and uterine contraction are the same, but a trustworthy method of assay of the former should be useful. Hitherto, the difficulty has been that successive doses of pituitrin produce a diminishing rise, or even a fall, of blood-pressure, and therefore samples cannot be compared with certainty In part this is due to the presence in the extract of a substance causing a fall of pressure; this can be removed by alcoholic extraction of the gland extract, or its formation prevented by placing the gland in cold acetone, as soon as it is removed from the body. Apart from this, however, frequent injections of a depressor-free extract produce diminishing effects until a complete immunity is obtained. This can be obviated by spacing the injections at wider intervals The test object recommended is the spinal cat, and the extract must be depressor-free, since it is possible that the substance which causes a fall of pressure in the anæsthetised animal causes a small rise in the spinal preparation If a dose which is about half the maximum, and produces a rise of pressure of 55 mm. Hg, is injected every hour, a 10 per cent. discrimination between two samples is perfectly possible, since the effect of the previous injection has worn off in this time. The chief objection to the method appears to be in the time taken, since injections are only possible every hour, the guinea-pig's uterus, on the other hand, can receive five or six separate doses in this time A further difficulty is that the preparation may vary slightly in sensitiveness during the course of an experiment, but this may be overcome by comparing the unknown only against adjacent injections of the standard.

The standardisation of insulin is an even more complicated problem Its effect is to enable the tissues to utilise more carbohydrate both in health and in diabetes, when the pancreas is diseased, the simplest observation to make which shows this increased utilisation is an examination of the sugar of the blood, which falls after a dose of insulin But if it falls too much, unpleasant symptoms, including convulsions, are produced

Macleod and Orr (*J Lab Clin Med*, 1924, vol. 9, p 591) have described in detail a method for assaying insulin based on the fall in blood sugar in rabbits. Owing to the variability in the response of different animals, a number must be used in any single test, the conditions must also be standardised so far as possible since the level of the blood sugar is influenced by many factors, thus the animals must be starved for the preceding 24 hours, must not have a blood sugar much above 0 1 per cent, and must not be used for more than two or three months, when they become refractory and put on weight At least four estimations of the blood sugar are necessary in each animal, and the time occupied is considerable, hence a simpler method, if as accurate, would be preferable, and Margaret Cheadle (*Austral J. Exp Biol and Med. Sci*, 1924, vol 1, p. 121) has utilised the incidence of convulsions as a method of assay In this case mice are used as test animals, and minute doses of insulin injected, and the incidence of convulsions in each group injected with the same dose noted After injection the animals must be kept at body temperature, otherwise they do not regularly develop convulsions. If a mouse unit of insulin be defined as the amount necessary to give convulsions in 60 per cent. of animals after subcutaneous injection, it must be correlated with the present standard, which is based on the fall of blood sugar in a rabbit, one unit being defined as the amount necessary to lower the blood sugar of a 2-kilo. rabbit to 0·045 per cent. in 5 hours. The unit used clinically is $\frac{1}{4}$ of the rabbit unit. The author finds 167 mouse units equivalent to 1 rabbit unit.

This somewhat cumbrous method of expressing the strength of insulin is necessary if comparable results are to be obtained in different tests with animals of varying weight A further complication has been found, in that some samples of insulin seem to contain a substance which may be described as an anti-insulin. de Jongh (*Biochem Jour*, 1924, vol 18, p. 833) gives an account of its properties: its presence is only revealed when small doses of insulin are injected, as in rabbits, but in man its influence appears to be small. It is apparently of a protein nature, and as the purification of insulin in the process of manufacture has been made more complete, the samples on the market at present appear to be free from it. In any case it is an illustration of the difficulties encountered by those who have to measure the strength of substances of unknown composition and isolated only in an impure condition

Heterogeneous Equilibria.

THREE papers by Mr. J. A V. Butler, in the Transactions of the Faraday Society, February 1924, and two in the *Phil Mag*, October and November, deal with problems of equilibrium at the boundaries between solids and liquids, and between two solids. The methods of statistical mechanics are applied in each case, and the first paper, "Conditions at the Boundary Surface of Crystalline Solids and Liquids," well illustrates the way in which other problems are dealt with

A diagram shows how the attractions of the solid and of the liquid on a molecule of the solute and their resultant are assumed to vary with distance from the surface, with a balance point at which the two opposing forces are equal A molecule from the surface will escape if, owing to thermal agitation, it has sufficient kinetic energy to carry it past the balance point Molecules which reach the balance point from the interior of the liquid are attracted to the surface. An equation is deduced, similar to that of Langmuir, for the number of molecules reaching the boundary surface of a gas with kinetic energy greater than a certain quantity λ This equation, which contains the mean collision frequency, applies to the molecules moving in the liquid towards the surface, but not directly to the molecules in the surface, the only motion of which is a vibration about an equilibrium position The mean collision frequency is replaced in the equation for these molecules by a vibration frequency ν

An expression for the solubility is thus obtained which leads to the le Chatelier-van 't Hoff equation for change of solubility with temperature, one of the terms of which is the heat of saturated solution. Assuming that ν is the characteristic vibration frequency of the solid, as determined by *rest strahlen*, and that the work done by the molecules from the surface layer, per gram molecule, in reaching the balance point is equal to the total heat absorbed in solution, unless this is less than the latent heat of fusion, when the latter is used, the author applies his equation to the alkaline chlorides. In this way he obtains results which are of the right order of magnitude.

Similar methods are employed in a discussion of the E.M.F produced when a metal is dipped into a solution containing its ions. The process is regarded as essentially a solubility phenomenon. In the solution of a salt crystal, made up of positive and negative ions, both kinds are dissolved, but it is assumed that in the case of a metal, only the positive ions pass into solution, while the electrons which go to build up the crystal lattice are left behind. Equilibrium is attained when equal numbers of positive ions are dissolved from and deposited at the surface in unit time. The negative charge due to the free electrons left on the metal retards the solution and assists the deposition, and to this extent the phenomena of salt solution are modified. This is taken into account in the mathematical treatment of this case, with the result that a formula is obtained for the potential which, in form, resembles that of Nernst. Instead of being based on osmotic pressure, however, it depends on the heat absorbed in the passage of the metal ions into solution, and on quantities defining the statistical conditions The values calculated from the formula are again of the right order of magnitude

In a third paper Mr. Butler proposes a kinetic theory of reversible oxidation potentials at inert electrodes dipped into a solution containing two substances related by a simple oxidation reduction process An expression is obtained for the numbers of each of the two ions, M′ and M″, contained in the solution adsorbed by each square centimetre of the electrode, using a mathematical method similar to that applied above The reaction between each of these ions and the electrode is considered, one of them tending to gain an electron and the other to lose one, and an expression for the oxidation potential is obtained This is determined by the ionisation potential corresponding to the loss of an electron by the reduced molecule, the difference in the energies of hydration of the two substances, the thermionic work function of the metal and two statistical constants

Mr. Butler deals with metal contact potentials in a paper in the *Philosophical Magazine* for October. He obtains an expression for the potential difference at the surface of a single metal in a closed space containing an electron atmosphere, the loss of electrons from the surface of the metal being balanced by the gain of electrons from the atmosphere He then considers the case of two metals in the electron atmosphere, but not in contact, and finds that though the surface P.D. of each metal depends on the electron atmosphere *concentration*, the difference for any two metals is characteristic of them If the metals are brought into contact, the conditions at the surfaces not in contact are unaltered, and if there is to be no continuous flow across the junction, there must be a P.D. at the junction equal to the intrinsic P.D of the metals. The Peltier heat effect at the junction is explained, and the various equations of the thermionic effect are co-ordinated On certain assumptions they lead to the conclusion that the Thomson P.D is the same for the same difference of temperature in all conductors.

Finally, in a paper on the seat of the electromotive force of the galvanic cell (*Phil Mag*, Nov.) Mr. Butler co-ordinates the results of his previous papers, and derives a statistical theory of the galvanic cell The existence of large metal contact P.D.'s is not inconsistent with the correspondence between the E.M.F. of the cell and the energy of the chemical reaction. The metal contact P.D. theory, the chemical theory, the Nernst theory of metal electrode potential differences and the relation between E.M.F. and total energy change expressed by the Gibbs-Helmholtz equation are included in the new theory as different aspects of the whole truth.

University and Educational Intelligence.

BIRMINGHAM.—The annual meeting of the Court of Governors was held on February 26. The report of the Principal (Mr. C, Grant Robertson), which was presented to the meeting, shows that during the last session the number of students diminished slightly as compared with the number for the preceding session. The total, however, is still 50 per cent higher than in the year before the War. An encouraging fact is the increase in the proportion both of full-time degree students and of post-graduate students

New buildings are to be erected at Edgbaston for the Petroleum Mining Department, and it is hoped that they will be ready for occupation by October next The transfer of this department will give room for the expansion of the Department of Coal Mining. An effort is being made to provide further buildings, which are urgently needed, for an extension of the Department of Chemistry and for the removal of the Biological Departments to Edgbaston, but the great increase in the cost of building is a very serious obstacle to be overcome

Two important events of the year have been the creation of a chair of law (of which Mr C F. Smalley-Baker is the first occupant) and the establishment of a readership in geography

CAMBRIDGE.—Dr J H Jeans has been appointed Rouse Ball lecturer in mathematics for the present academic year

LONDON.—Mr J. H Dible has been appointed to the University chair of pathology tenable at the London School of Medicine for Women Prof. Dible studied at the University of Glasgow In 1919 he was appointed lecturer in pathology in the University of Manchester and assistant pathologist to the Manchester Royal Infirmary, and in 1921 lecturer in bacteriology and senior assistant in the Department, carrying out work both for the Ministry of Health and for public bodies and hospitals in Manchester and adjacent towns

The title of reader in economics in the University has been conferred on Dr. Hugh Dalton, in respect of the part-time appointment which he will hold at the London School of Economics from August 1, on his resignation of the Sir Ernest Cassel readership in commerce. The title of emeritus professor of hygiene in the University has been conferred on Prof H, R Kenwood, who held the Chadwick chair of hygiene at University College from 1904 to 1924, and the title of emeritus professor of medicine at University College on Sir John Rose Bradford, who occupied at that College the chair of materia medica, pharmacology, and therapeutics from 1895 to 1903, and the chair of medicine and clinical medicine from 1899 to 1907.

The School of Pharmacy of the Pharmaceutical Society of Great Britain has been admitted as a School of the University in the Faculty of Medicine (in pharmacy only) for a period of five years as from January 1 last.

The following Doctorates have been awarded:—*D.Sc.* (*Biochemistry*): Mr. Robert Robison (Lister Institute of Preventive Medicine), for a thesis entitled "Hexosephosphoric Esters and their Physiological Functions"; *D.Sc.* (*Chemistry*): Mr. G. R. Clemo, for a thesis entitled "Strychnine and Brucine," and other papers; *D.Sc.* (*Physics*): Mr. Frederick Simeon, for a thesis entitled "1. The Carbon Arc Spectrum in the Extreme Ultra-Violet; 2. Note on the Striking Potential necessary to produce a Persistent Arc in Vacuum," and other papers; *Ph.D.* (*Science*)—Mr. L. Horton (Imperial College—Royal College of Science) for a thesis entitled "The Effect of the Alteration of the Carbon Tetrahedral Angle upon the Ease of Formation of Heterocyclic Rings", Mr A B Manning (Imperial College—Royal College of Science) for a thesis entitled "Researches on Gelatin", Mr E. G Richardson (East London College) for a thesis entitled "Aeolian Tones, Vibrations excited by Fluid Motion", Mr. J W Baker (Imperial College—Royal College of Science) for a thesis entitled "The Formation and Stability of Compounds containing Associated Alicyclic Rings (highly strained Rings)"; Mr I Cohen (Middlesex Hospital) for a thesis entitled "Observations on Variations in Blood and Urinary Diastase, with special reference to Meals and Starvation", Mr. E C. Dodds (Middlesex Hospital) for a thesis entitled "Observations on the Body Diastase," and other papers, Mr. W Russ (University College) for a thesis entitled "1 The Phosphate Deposits of Abeokuta Province 2 The Riebeckite Rocks of Northern Nigeria", Mr E R Trotman (University College, Nottingham) for a thesis entitled "The Preparation of Quaternary Hydrocarbons"

Prof E Barclay-Smith, professor of anatomy since 1915, and Prof O W. Richardson, appointed Wheatstone professor of physics in 1913 and relinquishing that appointment in 1924 on appointment as one of the Yarrow research professors of the Royal Society, have been appointed fellows of King's College

---

A CONVERSAZIONE will be held at the Chelsea Polytechnic, Manresa Road, London, S W 3, on March 13 The laboratories and workshops will be open for inspection, 6.30-10 30 P M

APPLICATIONS are invited for a research studentship in tropical medicine in connexion with the government of the Federated Malay States The annual value of the studentship is 700*l* Particulars of the post, and forms of application, are obtainable from the Private Secretary (Appointments), Colonial Office, Downing Street, S W 1.

APPLICATIONS are invited by the Glamorgan Agricultural Committee for the position of instructor in dairy and poultry husbandry Special knowledge of poultry keeping on the farm, and dairy farming (including clean milk production), and good technical qualifications are expected from candidates Application forms (returnable by March 16 at latest) can be obtained from the Director of Agriculture, 5 Pembroke Terrace, Cardiff

THE work of research has received a noteworthy and welcome stimulus at Armstrong College, Newcastle-on-Tyne An anonymous gift of 12,000*l* enabled the Council to establish a Research Endowment Fund in 1923, and the Committee which was appointed to administer the fund has published its first annual report. The Committee records its intention to utilise the proceeds to help members of the College and others with their researches by providing temporary or partial relief from teaching or by arranging for assistance, and by defraying the cost of books, apparatus, travelling and other expenses thus to supplement the resources already in operation and not to supersede the provision available for the training of post-graduates These considerations have guided the Committee in allocating grants during the first year. The Committee has also been able to arrange for a grant being given by the Newcastle and Gateshead Water Co. for a special research; and intimates a desire to advise or to co-operate with industrial firms and corporations desiring investigations in any particular direction. The opportunity has been taken to give a list of papers which have been published by members of the College staff during the year, and from this, although it is not exhaustive,

it is evident that all departments are actively engaged in research.

LORD EMMOTT presided at an important meeting held in the Regent Street Polytechnic, London, on Friday, February 27, when the question of an inquiry into the relationship of technical education to other forms of education and to industry and commerce was discussed. The case for the inquiry was presented by Lord Emmott and Mr J Wickham Murray (Joint Committee of the Three Technical and Art Associations) Their speeches indicated that, although technical education forms the contact-point between education and industry, its place in the national system of education is undefined Since, in any area, the technical institute draws its pupils from all other types of school, it is essential—if waste and overlapping are to be prevented—that its relationship to those other schools should be clearly understood Further, since technical education (including applied art) is the contact-point with industry, it is very necessary that more definite relationships be established if education is successfully to be linked to the world's work Educationists and industrialists seem more than ever to be sharply critical of each other's aims and methods, but no comprehensive attempt has been made towards sane and tolerant discussion of mutual problems It is now proposed to bring together not only primary, secondary, technical, and university teachers, but also employers, representative industrial and commercial bodies, and learned institutions Among the bodies represented at the meeting were the British Association, the Federation of British Industries, professional engineering bodies, teachers' associations, Institutes of Chemistry and Physics, and the British Science Guild The meeting finally resolved that the inquiry was desirable, and that the bodies represented be asked to appoint representatives to a committee whose work will be the preparation of the ground which the inquiry will cover

THE Parliamentary Grant (ordinary) for universities and university colleges in the British Isles, which was increased in 1921 from 1,000,000*l.* to 1,500,000*l.* (including 110,000*l* for Irish universities), did not escape the attention of the Geddes Economy Committee For each of the two succeeding years it was (for Great Britain only) 1,169,000*l*, and for 1924–25 it is 1,122,570*l.*, excluding the new grants (amounting now to 120,000*l*) for Oxford and Cambridge. Last November a deputation from all the universities of Great Britain, except Oxford and Cambridge, headed by Sir Donald MacAlister, waited upon the Chancellor of the Exchequer to urge the raising of the grant to 1,500,000*l*. A letter on this subject from Mr. Churchill to Lord Balfour, who introduced the deputation, was published in the *Times* of March 2. After reciting the salient points of the case presented by the deputation, which was very sympathetically received, the letter announces the stabilisation of the grant for five years at 1,380,000*l* (excluding provision for Oxford and Cambridge) For this relief the universities will, undoubtedly, echo the expression of thanks conveyed in Lord Balfour's reply, and if their gratification is tempered by regret that Mr. Churchill has so firmly required them to forgo the expectation of any further increase for at least five years, they cannot fail to recognise that even this condition carries with it compensations, among which may be reckoned the greater precision and therefore effectiveness with which they will be able to define their needs when appealing for aid to local authorities, to alumni, and to the public. The amount at which the grant has now been fixed (1,380,000*l.*) is approximately 39 per cent of the aggregate annual expenditure of the universities concerned in 1922–23.

Early Science at Oxford.

March 7, 1683/4.—After ye reading of ye Minutes, Dr. Plot was pleasd to acquaint ye Society that he had lately calcined clay-ochre, and stone-ochre (both which were yellow, from Shotover) about thirty-six hours, but neither of them applyed to ye Magnet; which gave ye Doctor grounds to question, whether yellow ochres will be affected by ye Magnet after any calcination, how long soever Tobacco-pipe clay, Marl, Bole armeniac and Terra Lemnia were calcined ye same space of time, but none of them applyed to ye Magnet

Then Dr Pit was pleased to inform ye Society that Oyl Olive is uncapable of any ebullition after it has spent its aqueous parts, which rise in bubbles, for, being pressed with a stronger fire, than what made water boyl over a large vessell, it could not be sensibly raised, although ye heat of ye oyl was so intense, that, being removed from ye fire, it broke out into a flame, and continued to do so after six or seven suffocations of ye flame Butter boyls over till its serous parts are evaporated, but afterwards, though pressed with a very great heat, is no more capable of ebullition, than so much melted lead

A Report of ye consultation, held for ye drawing up Articles, for ye better Regulation of ye Society, was offered, but ye examination of it was deferred, till ye next meeting which was ordered to be on ye Tuesday following, at 2 after dinner

March 8, 1686/7.—Dr Plot reported on the prices of commodities in the time of King John, which he had extracted from a Dugdale manuscript in the Ashmolean Library Mr President wrote to Mr. Halley several arguments against Mr Hooke's late hypothesis of the change of the surface of ye Earth.

March 9, 1685/6.—Dr. Lister of London communicated a paper of Georgics concerning ye improvement of Sandy land by ye *Vicia multiflora nemorensis perennis sive Dumetorum* I B which is practised both in Yorkshire and Staffordshire

March 10, 1684/5.—Mr Maunders speaking of ye dismall weather on ye 23rd of December last, says, that above eighty Persons were found killed by it, in Wiltshire and Dorsetshire. Some died suddenly, others by degrees: some, that escaped, were so tormented in their hands, and face (parts exposed to ye cold) that, as they recovered, and ye swellings abated, the skin peeled off, and they were some days without ye use of their limbes, and sometimes of their senses.—Part of Mr. King's ingenious discourse of Bogs was read; and also Mr Aston's letter relating that ye Savages of Canada get from Maple juice a sugar as sweet as that of ye Canes

March 11, 1683/4.—Salamander's wool was observed, by Mr Ballard, to be separated from ye earthy parts, to which it is joynd, by heating the Amianthus and bruising it into peices. It was ordered, that some attempts should be made, towards ye working this wool into a thread, that so we may [if it be possible] either trace out ye methods of ye Antients, or equall their inventions with new ones in this kind; for ye effecting of which, Dr. Beeston was pleased to take on him, ye trouble of employing some curious hand, suitable to so ingenious a design.

March 13, 1687/8.—Mr. Cole of Bristoll discoursed concerning the Descent of Spiders with their webs, taken in the County of Wilts in September and October 1686, with an occasionall discourse about Spontaneous Generation wherein is given allso an account of people that have been witnesses of the raining of frogs and crabs.

Societies and Academies.

LONDON.

Royal Society, February 26.—E. H. **Starling** and E. B. **Verney**: The secretion of urine, as studied on the isolated kidney The mechanism of urinary secretion in mammals has been studied by perfusing the dog's kidney with the heart-lung preparation The glomeruli filter from the blood plasma its non-protein constituents. Hydrocyanic acid suspends tubular activity, while the action of hydrocyanic acid is reversible. Urea, sulphate, and, when present in the serum, phenosulphonephthalein, are secreted by the tubule cells into the glomerular filtrate. Water, chloride, bicarbonate, and glucose are re-absorbed by the tubule cells from the glomerular filtrate. Water appears to be re-absorbed lower down the tubule than chloride Pituitrin causes a marked increase in the percentage and absolute amounts of chloride and a decrease in the amount of water eliminated Substances of this type normally regulate the output of water and chloride in the intact animal, and the characters of the urine secreted by the isolated organ are due in large part to their absence.—F. **Eicholtz** and E. H. **Starling** The action of inorganic salts on the secretion of the isolated kidney Calcium working on a background of potassium leads to an increase of chloride excretion and water output, due to decreased re-absorption in the tubules. These salts, if given separately, have no definite effects Inorganic phosphates decrease the output of water and chlorides by turning the calcium ion into a colloidal form. To this colloidal form the glomerulus membrane is impermeable Cyanide increases the permeability of the glomerulus membrane and allows the colloidal phosphates to appear in the urine.—G. V. **Anrep**. A new method of crossed circulation The method consists in an arterial anastomosis between a heart-lung preparation and the descending aorta or the brachio-cephalic artery of another animal Thus the part of the animal connected with the heart-lung preparation receives its blood supply from the latter, while the remaining part of the animal continues to be fed by its own heart The blood flow and the blood pressure of the perfused part of the animal is therefore under complete control.—G. V. **Anrep** and I. de B. **Daly**. The output of adrenaline in cerebral anæmia, as studied by means of crossed circulation. In this condition there is an increased liberation of adrenaline from the suprarenal glands, which is due to a true secretion and not to redistribution of blood, and the increased secretion disappears after denervation of the suprarenal glands.—G. V. **Anrep** and E. H. **Starling**: Central and reflex regulation of the circulation. Mechanical rise in blood pressure in the brain inhibits the vasomotor centre and stimulates the cardio-inhibitory, the two centres acting synergetically to produce lowered pressure Asphyxia by cerebral anæmia stimulates both vasomotor and cardio-inhibitory centres, the centres acting antagonistically, not synergetically. Andrenaline (small doses) introduced into head circulation causes slowing of heart and fall of pressure in lower half of animal. Measurement of pressure in Circle of Willis shows these effects are due to increased circulation through medullary centres, and cannot be ascribed to direct excitation of centres by adrenaline itself. The effects are analogous to, and produced in the same way as, those obtained on increasing pressure in head circulation.—K. **Furusawa**: Muscular exercise, lactic acid, and the supply and utilisation of oxygen. Part IX. Muscular activity and carbohydrate metabolism in the normal individual. Results obtained are: On normal diet, carbohydrate only is responsible for the process of contraction and recovery from it. As duration of exercise is prolonged respiratory quotient of excess metabolism falls slowly, indicating that some substance other than carbohydrate is being called upon. On fatty diet, short-lived muscular exercise is performed at expense only of carbohydrate, as on normal diet. In long-continued exercise, fat takes part more quickly than on normal diet. In exercise of short duration, in which no change in general metabolism of body as a whole might be expected, the human body acts as though it were an isolated muscle, in which carbohydrate is the only substance oxidised, as shown by Meyerhof. The primary fuel of contraction, therefore, in human muscle is carbohydrate, and fat or protein is presumably used to replenish carbohydrate store disappeared.—A. **Hunter** and J. A. **Dauphinee**. (1) Quantitative studies concerning the distribution of arginase in fishes and other animals. (2) An approximative colorimetric method for the determination of urea with an application to the detection and quantitative estimation of arginase.—J. J. R. **Macleod** and N. A. **McCormick**: The effect on the blood-sugar of fish of various conditions, including removal of the principal islets (isletectomy).

Royal Microscopical Society, January 21.—A. Chaston **Chapman** The yeasts a chapter in microscopical science (presidential address) Some new technique, such as the use of ultra-violet light, applied to the investigation of the cytology of the yeast cell, might, in the hands of expert cytologists, yield results equally valuable to industry and to general biology The views of Cramer and others as to the dependence of intra-cellular enzymic activity on surface tension was referred to, and reasons were given for supposing these surface tension effects to be operative in connexion with some industrial fermentation processes The yeast cell is, in fact, a chemical laboratory of the highest efficiency, and of the most remarkable character, and if the processes of building up and breaking down, which are so quietly and so regularly occurring in a single cell of yeast, could be understood and artificially imitated, we should be not only within measurable distance of a new organic chemistry, but also appreciably nearer to an understanding of that greatest of all problems, the nature of life

Linnean Society, January 22.—Miss M. S. **Johnston**: Calcareous deposits (rhizocretions, Kindle) round roots of Canadian birches in Pleistocene sands. The concretion is considered to be due to the action of humic acid from the roots segregating the lime constituents in the sand.—R. D'O. **Good**. The flora of Canada. As in Britain, the largest plant families are the Compositæ, Gramineæ, Cyperaceæ, Leguminosæ, Rosaceæ, and Labiatæ, and the first named is very much larger than any of the others In traversing the country from east to west, four main vegetational types are encountered: the Eastern forest, the prairie, the mountain, and the Pacific littoral The southern limit of the Pleistocene ice was well down in the United States, and the present flora of Canada is therefore an immigrant flora developed in the geologically short time since the retreat of the ice.—J. **Munro**: Canadian forests and forestry. There are four climatic belts between the east coast and British Columbia.

CAMBRIDGE.

Philosophical Society, January 19.—H. F. **Baker**: A transformation of Segre's figure in space of four dimensions; the equation of Kummer's surface. There is a figure, first studied by Stéphanos in the

theory of circles, but studied particularly by Segre as a figure in four dimensions; consisting of fifteen lines meeting by threes in fifteen points. The figure is of great interest, as being the centre of a discussion of many well-known surfaces; the cubic surface, the cyclide, Kummer's surface, and so on. In this figure there are also six sets of fives of the lines, each being taken twice over, called sets of *associated* lines. The present paper finds a transformation from the lines of the figure to the joins of six points in space of *five* dimensions—a set of associated lines becoming the joins of one of the six points to the other five. Intimately related therewith is the expression of the equation of a Kummer surface by a sum of five squares. The coefficients of these squares are invariants of the discriminantal equation of the primary quadratic complex.—R. **Vaidyanathaswamy**: On simplexes doubly incident with a quadric. The generalisation of the figure representing a double six of lines in five dimensions, wherein a hexad is both inscribed to and circumscribed about a quadric.—H. G. **Green**: The classification of conicoids by their generators. An actual method of reduction of the equation of a conicoid to a form showing the character of the surface.—R. **Whiddington**: On the positive flash in vacuum discharge tubes. Moving striations previously observed in the rare gases were reinvestigated in the case of pure argon. The bright flashes travelling from the anode with velocities depending on the pressure show no Doppler effect. The luminous radiation seems to be excited by invisible radiation given out by positive ions as they travel along the tube.—E. C. **Stoner**: The structure of radiation. On the assumption of conservation of energy and linear momentum, the evidence in favour of radiation being constructed of linearly directed, spatially localised quanta is held to be conclusive. Further properties, which are not physically unreasonable, must be postulated of these quanta in order that interference phenomena may be possible.—Major P. A. **MacMahon**: The symmetric functions of which the general determinant is a particular case.

MANCHESTER.

Literary and Philosophical Society, January 20.—W. **Robinson**. On proliferation and doubling in the flowers of *Cardamine pratensis* L. Specimens of *C. pratensis* showing two main types of abnormality were found in meadows near Cheadle Hulme, Cheshire, in June 1923, one of which was similar to the double-flowered form, arising by proliferation of the ovary, described most frequently by previous observers, and the other, a less completely double-flowered specimen. Microscopic investigation showed that, in both types, proliferation took place by the meristematic activity of a growing-point at the base of the ovary, of a flower which was otherwise normal. In one case, however, the ovary itself was carried up on a stalk produced by the growth activity of tissues immediately below the base of the ovary, but outside this; in the other specimen all the growth took place within the ovary from the base of this, and the meristematic growing-point was carried up to about the middle of the pod-like structure. The doubling seen in *C. pratensis* has recently been spoken of as a mutation from the more normal single form, but Goebel has stated that by cultivating plants of the double form in sandy soil they completely lost the character. By vegetative multiplication from the original specimens collected wild at Cheadle Hulme, it has been possible to cultivate plants showing variations, both in the character and degree of the doubling. Further work will show whether the plasticity of *C. pratensis* is such that doubling can be produced under experimental conditions in a single-flowered form by nutritional changes as Goebel has suggested, or whether, as seems more likely, the double-flowered and single-flowered forms are two different races with distinct hereditary complexes.

PARIS.

Academy of Sciences, January 26.—G. **Bigourdan**: The propagation of Hertzian waves to great distances. The order of magnitude of the perturbations of this propagation. A table is given showing the results of the reception of the Bordeaux time signals for 1923, by Helwân (near Cairo), Washington, Ottawa, Greenwich, Paris and Uccle.—H. **Vincent**: The urinary elimination of the *Bacillus coli communis* and its hæmatogen origin.—P. **Bazy**: Remarks on the preceding communication.—Maurice **Lugeon**: The presence of fossilised organic bodies in the marbles of Uruguay. Fragments of echinoderms and molluscs have been recognised in marble from Nueva Carrara; this is of interest, as being the first occasion of the discovery of fossil remains in this crystalline deposit.—Bertrand **Gambier**: The continuous deformation of surfaces, isometry and applicability.—Mlle Thérèse **Leroy**: A new method for the determination of the working costs and a tariff for railway transport. A new tariff scheme has been developed as the result of a mathematical study of data from eighty years' actual railway experience.—**Andrieau**: The Andrieau motor. A detailed description of the mode of working, construction, and experimental results of a new design of internal combustion motor.—Carl A. **Garabedian**: Solution of the problem of the heavy rectangular plate, framed or open, carrying a charge uniformly distributed or concentrated at its centre.—A. **Alayrac**: The theoretical study of motorless flight in a variable horizontal wind.—Ernest **Esclangon**: The eclipse of the sun of January 24, 1925, observed at the Strasbourg Observatory. The time of first contact, deduced from two series of independent measurements of the chord of contacts, was $15^h\ 3^m\ 37^s$.—L. **d'Azambuja**: Observation of remarkable protuberances, made at the Meudon Observatory, January 24, 1925, before the eclipse of the sun. On January 24 a series of spectroheliograms of the lines K_3 (calcium) and H_3 (hydrogen) was taken continuously. A photograph taken at 11.10 A.M. with the calcium line showed the existence in the N.W. quadrant, of a fan-shaped group of protuberances in the form of jets, the largest of which attained a height of one-fifth of the solar radius. Its development was very rapid, since photographs at 10.40 A.M. and 12.20 P.M. did not show it.—J. **Guillaume** and Mlle. M. **Bloch**: Observation of the partial eclipse of the sun of January 24, 1925, made at the Lyons Observatory. Clouds interfered with observations. First contact was noted at $15^h\ 4^m\ 36^s{\cdot}2$.—P. **Chofardet**: Observation of the eclipse of the sun of January 24, 1925, at the Besançon Observatory. Time of first contact at $15^h\ 3^m\ 48^s{\cdot}8$.—F. **Holweck**: Determination of the critical potential L_{III} of argon. Discussion of the precision of this measurement and of analogous measurements.—Ed. **Friedel**: Smectic bodies and X-rays. The existence of a stage (smectic state) intermediate between the solid crystal and the true liquid has been indicated in an earlier communication for certain oleates. These conclusions have been questioned, and additional experiments on the radiograms furnished by ethyl *p*-azoxy-benzoate, and ethyl azoxy-cinnamate have been made. The results confirm the conclusions previously given.—F. **Baldet**: The spectrum of carbon monoxide at very low pressure; the so-called comet-tail spectrum.—Ernest **Bengtsson** and Erik **Svensson**: The conditions

of the appearance and structure of the silver bands, λ3330 and λ3358.—F. Croze: The structure of the line spectra of ionised nitrogen and oxygen.—Jean Jacques Trillat: The molecular orientation of the fatty acids.—Herbert Brennen: Chemical studies on the isotopes of lead. A partial separation of the isotopes of lead by the action of the Grignard reagent on lead chloride has been recently described by Dillon, Clarke, and Hinchy. This work has been repeated, and no evidence of separation of isotopes was obtained.—Georges Fournier: The absorption of the β-rays by matter. If μ is the coefficient of absorption and ρ the density of the material, then experiments with six materials show that the relation $\mu/\rho = a + bN$ (where N is the atomic number) is valid.—A. Bigot: Clays, kaolins, etc.—L. Blanc and G. Chaudron: The magnetic study of the stable form of the sesquioxides of iron and chromium. The magnetic susceptibility of Fe_2O_3 and Cr_2O_3 as a function of the temperature is given in graphical form. the results are difficult to interpret.—André Graire: The reduction of the oxides of nitrogen in the presence of sulphuric and sulphurous acids.—Marcel Godchot and Pierre Bedos. The chlorination of para-methyl-cyclohexanone.—Ch. Courtot and P. Petitcolas: Syntheses of 9-fluorenylamines.—J. Barthoux: Description of a new mineral, dussertite. This mineral, found at Djebel Debar, is an arsenate of the composition $(FeAl)_3(CaMg)_3(OH)_9(AsO_4)_3$. The full chemical analysis, physical and mineralogical description are given.—Pierre Bonnet: The problem of the Trias of the Avallonnais and Auxois.—Pierre Dangeard: Limits of the submerged plant growth of Lake Annecy at varying depths.—P. Mazé: The plurality of the products of photosynthesis, deduced from the study of the gaseous exchanges between the atmosphere and the whole plant.—Mlle. Sara Bache-Wüg: The vacuome of *Erysiphe graminis*.—P. E. Pinoy: Concerning the cancer of plants or crown gall. L. Ravaz and G. Verge: A disease of the vine, excoriosis.—Mme. Jean Francois-Perey: The influence of the culture medium on protozoa counts in soil. The influence of the culture medium is marked; an extract of the earth with gelose is recommended as giving the most trustworthy results.—C. F. Muttelet: Study of the development of the pea; from the point of view of conservation for food.—Vittorio Pettinari: The toxic action of *Amanita phalloides*.—Georges Bourguignon and J. B. S. Haldane: The evolution of chronaxy in the course of the crisis of experimental tetany by voluntary hyperpnea in man.—A. Malaquin: The segregation, in the course of ontogenesis, of two primordial sexual cells; origin of the germinal descent in *Salmacina Dysteri*.—Robert Weill: Foci of formation and ways of migration of the nematocysts of *Halyclistus octoradiatus*. The existence, along their path, of selective reservoirs.—J. Chaine: Remarks on the penian bone.—Armand Dehorne: The petaloid expansions of the leucocytes of the Chetopoda. The case of *Leydenia Gemmipara*.—Ph. Joyet-Lavergne: The lipoids and fats of the Sporozoa.—Edouard Chatton and André Lwoff: The physiological determinism of the phases of the cycle of the infusorian *Spirophrya subparasitica*.—A. Berthelot and G. Ramon: The agents of transformation of the toxins into anatoxins. Toxins can be converted in various ways into substances deprived of toxic power, but retaining the power of flocculation (*in vitro*) and immunising power (*in vivo*). These products are described as anatoxins, and the action of a large number of chemical compounds on the diphtheria toxin has been studied from this point of view. The most effective reagents for the production of the diphtheria anatoxine proved to be acrolein, crotonaldehyde, acetaldehyde and hexamethylenetetramine.

Official Publications Received.

Department of the Interior: United States Geological Survey. Bulletin 751-E: The Scobey Lignite Field Valley, Daniels, and Sheridan Counties, Montana. By Arthur J. Collier. Pp. v + 157-280 + plates 24-39. (Washington: Government Printing Office.)

Department of the Interior. United States Geological Survey. Professional Paper 132-F. Relations of the Wasatch and Green River Formations in North-Western Colorado and Southern Wyoming, with Notes on Oil Shale in the Green River Formation. By J. D. Sears and W. H. Bradley. Pp. ii+93-107+2 plates. *Professional Paper* 132-G: Discovery of a Balkan Fresh-water Fauna in the Idaho Formation of Snake River Valley, Idaho. By W. H. Dall. Pp. ii+109-115+1 plate. Professional Paper 132-H. The Resuscitation of the Term Bryn Mawr Gravel. By F. Bascom. Pp. 117-119. (Washington: Government Printing Office.)

Diary of Societies.

SATURDAY, MARCH 7.

ROYAL SOCIETY OF MEDICINE (Otology Section), at 10.30.

ASSOCIATION OF TECHNICAL INSTITUTIONS (Annual Meeting) (at Institution of Mechanical Engineers), at 11 A.M.—Lord Emmott and Ppl. W. M. Varley: The Local College and its Relation to Surrounding Education Authorities.—G. Mavor: Training and Education for Apprenticeship.—J. E. Montgomery: The Working of the Schemes for National Certificates and Diplomas in Engineering.

INSTITUTION OF MUNICIPAL AND COUNTY ENGINEERS (Eastern and South Midland Districts) (at Town Hall, Ealing), at 2.35.—The Question of Regional Town Planning.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: The Counting of the Atoms (II.).

IPSWICH AND DISTRICT NATURAL HISTORY SOCIETY (at Ipswich).—Dr. F. W. Crossley-Holland: Science and the Criminal.

MONDAY, MARCH 9.

ROYAL SOCIETY OF EDINBURGH, at 4.30.—A. H. R. Goldie: Discontinuities in the Atmosphere.—Dr. A. P. Laurie: Stone Decay and the Preservation of Buildings (Address).—W. H. Watson: An Investigation of the Absorption of Superposed X-Radiations.—H. W. Turnbull and J. Williamson: The Minimum System of Two Quadratic Forms.—Prof. H. S. Allen: Note on Whittaker's Quantum Mechanism.—Marion C. Gray: The Equation of Conduction of Heat.

VICTORIA INSTITUTE (at Central Buildings, Westminster), at 4.30.—Rev. C. Gardner: Nature and Supernature.

BIOCHEMICAL SOCIETY (at Lister Institute), at 5.—F. W. Fox: The Cholesterol Content of Bile and its Bearing upon the Metabolism of Cholesterol and the Bile Acids.—J. R. Marrack: The Total Base Content of Plasma.—D. Hoffert and I. S. MacLean: The Action of Yeast on Lactic Acid.—E. H. Lepper and C. J. Martin: (a) The Influence

of Salt Concentrations on the C_H of Buffer Solutions as indicated by the Electrometric and Colorimetric Methods respectively: (*b*) Can the C_H of Mixtures of $NaHCO_3$ and CO_2 in High Dilutions be determined by the Hydrogen Electrode?

ROYAL SOCIETY OF MEDICINE (War Section), at 5.—Presentation, by Sir St. Clair Thomson, of the North Persian Forces Memorial Medal for 1923 to Wing-Commdr. H. E. Whittingham, for his Paper, Observations on the Life-History and Bionomics of *Phlebotomus papatasii*, written in conjunction with Flight-Lieut. A. F. Rook.—Wing-Commdr. H. E. Whittingham: The Treatment of Malaria by Novarsenobillon.

INSTITUTION OF ELECTRICAL ENGINEERS (North-Eastern Centre) (at Armstrong College, Newcastle-on-Tyne), at 7.15.—Major E. I. David: Electricity in Mines.

INSTITUTE OF CHEMISTRY (Birmingham Section) (at White Horse Hotel, Birmingham), at 7.30.—G. W. Marlow: Chemists' Agreements.

INSTITUTE OF METALS (Scottish Local Section) (at 39 Elmbank Crescent, Glasgow), at 7.30.—A. G. Lobley: Electric Furnaces.

SOCIETY OF CHEMICAL INDUSTRY (London Section) and INSTITUTE OF CHEMISTRY (London and South-Eastern Counties Section) (at Institution of Mechanical Engineers), at 8.—Sir Max Muspratt, Bart.: Chemistry and Civilisation.

SURVEYORS' INSTITUTION, at 8.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—A. F. R. Wollaston: The Sierra Nevada of Santa Marta, Colombia.

MEDICAL SOCIETY OF LONDON, at 8.30.—E. Clarke, A. F. Moore, Dr. J. Collier, and others: Discussion on The Fundus Oculi in General Medicine.

IPSWICH AND DISTRICT NATURAL HISTORY SOCIETY (at Ipswich).—Dr. F. W. Crossley-Holland: Science and the Criminal.

TUESDAY, MARCH 10.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. S. MacNalty: Epidemic Diseases of the Central Nervous System (Milroy Lectures) (II.).

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.15.—Prof. E. N. da C. Andrade: The Evolution of the Scientific Instrument (I.).

INSTITUTION OF PETROLEUM TECHNOLOGISTS (Annual General Meeting) (at Royal Society of Arts), at 5.30.—H. Barringer: Address.

INSTITUTION OF CIVIL ENGINEERS, at 6.—Prof. S. M. Dixon and F. W. Macaulay: Measurements of Discharge over a Rock-faced Dam.

INSTITUTION OF AUTOMOBILE ENGINEERS (at Royal Society of Arts), at 7.

INSTITUTION OF ELECTRICAL ENGINEERS (*Informal Meeting*), at 7.—C. W. Sully and others: Discussion on Illumination.

INSTITUTION OF ELECTRICAL ENGINEERS (North Midland Centre) (at Bradford Technical College), at 7.—H. W. Taylor: Three-wire Direct-current Distribution Networks: Some Comparisons in Cost and Operation.

INSTITUTION OF ELECTRICAL ENGINEERS (Scottish Section) (at North British Station Hotel, Edinburgh), at 7.—E. Hughes: Iron Losses in D.C. Machines.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—Annual General Meeting.

INSTITUTION OF ENGINEERS AND SHIPBUILDERS IN SCOTLAND (at 39 Elmbank Crescent, Glasgow), at 7.30.—G. A. Whiteman and A. Spittle: The Manufacture of Brass Condenser Tubes, with some Notes on an Alternative Alloy.

INSTITUTION OF AUTOMOBILE ENGINEERS (Coventry Graduates' Meeting) (at Broadgate Café, Coventry).

WEDNESDAY, MARCH 11.

INSTITUTE OF METALS (Annual General Meeting) (at Institution of Mechanical Engineers), at 10 A.M.—H. T. Angus and P. F. Summers: The Effect of Grain-size upon Hardness and Annealing Temperature.—S. L. Archbutt: A Method of Improving the Properties of Aluminium Alloy Castings.—U. R. Evans: Surface Abrasion as a Potential Cause of Localised Corrosion.—Dr. J. Newton Friend and J. S. Tidmus: The Influence of Emulsoids upon the Rate of Dissolution of Zinc in Solutions of Lead, Nickel, and Copper Salts.—At 2.—T. G. Bamford: Comparative Tests on some Varieties of Commercial Copper Rod.—R. Genders and G. L. Bailey: The Alpha Phase Boundary in the Copper Zinc System.—Dr. D. Bunting: The Influence of Lead and Tin on the Brittle Ranges of *Brass*.—E. A. Bolton: The Removal of Red Stains from Brass.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Prof. O. T. Jones: The Geology of the Llandovery District (Carmarthenshire).—G. Andrew: The Llandovery and Associated Rocks of Garth (Breconshire).—G. Andrew and Prof. O. T. Jones: The Relations between the Llandovery Rocks of Llandovery and those of Garth.

INSTITUTION OF CIVIL ENGINEERS (Informal Meeting), at 7.—J. S. Wilson: The Relative Importance and Nature of Secondary Stresses in Steel Structures.

INSTITUTION OF ELECTRICAL ENGINEERS (South Midland Centre) (at Birmingham University), at 7.—Major E. I. David: Electricity in Mines.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Graduate Section) (at Bolbec Hall, Newcastle-on-Tyne), at 7.—G. R. Hutchinson: Some Problems of the Motor Ship.

ROYAL SOCIETY OF ARTS, at 8.—E. Cammaerts: The Restoration of Public Buildings in Belgium.

INSTITUTION OF CHEMICAL ENGINEERS (at Institution of Mechanical Engineers), at 8.—Prof. A. L. Mellanby: Expansion and Compression Phenomena in Steam Jets.

INSTITUTION OF AUTOMOBILE ENGINEERS (North of England Centre) (at Leeds).

THURSDAY, MARCH 12.

INSTITUTE OF METALS (Annual General Meeting) (at Institution of Mechanical Engineers), at 10 A.M.—G. L. Bailey and R. Genders: The Density and Constitution of the Industrial Brasses.—A. L. Norbury: The Effects of certain Elements on the Electrical Resistivity of Copper.—Sir Thomas Kirke Rose: The Density of Rhodium.—Prof. T. Honda and Prof. R. Yamada: Some Experiments on the Abrasion of Metals.—Prof. T. Ishara: The Equilibrium Diagram of the Aluminium-Zinc System.

ROYAL SOCIETY, at 4.30.—Sir Charles Sherrington: Remarks on some Aspects of Reflex Inhibition.—E. G. T. Liddell and Sir Charles Sherrington: Recruitment and some other Features of Reflex Inhibition.—D. T. Harris: Studies on the Biological Action of Light.—Dr. H. Hartridge and F. J. W. Roughton: The Kinetics of Hæmoglobin. III.—*To be read in title only*:—S. B. Schryver, H. W. Buston, and D. H. Mukherjee: The Isolation of a Product of Hydrolysis of the Proteins hitherto undescribed.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. S. MacNalty: Epidemic Diseases of the Central Nervous System (Milroy Lectures) (III.).

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.15.—Dr. L. Hill: The *Biological Action of Light* (I.).

ROYAL SOCIETY OF MEDICINE (Comparative Medicine, Tropical Diseases, and Obstetrics Sections), at 5.30.—Special Discussion: Infective Abortion in Cattle and its Relation to Mediterranean Fever.

INSTITUTION OF ELECTRICAL ENGINEERS (Tees-Side Sub-Centre) (at Cleveland Technical Institute, Middlesbrough), at 7.15.—H. W. Taylor: Three-wire Direct current Distribution Networks: Some Comparisons in Cost and Operation.

INSTITUTION OF ELECTRICAL ENGINEERS (Irish Centre (Dublin)) (at Trinity College, Dublin), at 7.45.—Dr. J. F. Crowley: The Use of Electricity in the Chemical Industries, with particular reference to the Irish Free State.

INSTITUTE OF CHEMISTRY (Liverpool and North-Western Section) (at Liverpool University), at 8.—Prof. E. C. C. Baly: A Lecture Tour in America.

FRIDAY, MARCH 13.

ROYAL ASTRONOMICAL SOCIETY, at 5.—G. Prasad: The Progression of Stellar Velocity with Absolute Magnitude.—Dr. J. W. Nicholson: The Secondary Spectrum of Hydrogen.—Dr. H. Jeffreys: The Origin of the Solar System, in relation to Prof. Eddington's Theory of Stellar Luminosity.—E. A. Kreiken: The Density Function in the Milky Way.—Dr. J. K. Fotheringham: Visibility of Stars in Great Britain during the Solar Eclipse of 1925, Jan. 24.—T. Royds: Note on Spectroheliograms taken with Different Parts of the H_α line.—S. D. Tacherny: (*a*) Results of Micrometer Measures of the Position of Mars relative to the Star B.D. −4° 5913 on 1924, Dec. 5; (*b*) Occultations of Stars by the Moon, 1924.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 5.—J. P. Andrews: The Variation of Young's Modulus at High Temperatures.—Dr. E. G. Richardson: The Critical Velocity of Flow past Objects of Aerofoil Section.—Dr. J. Brebtano: A Focussing Method of Crystal Powder Analysis by X rays.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Reports to the Cutting Tools Research Committee.—Prof. E. G. Coker: The Action of Cutting Tools.—D. Smith and A. Leigh: Experiments with Lathe Tools on Fine Cuts, and some Physical Properties of the Tool Steels and Metal operated upon.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—F. Judge: Many Slides and a few Remarks.

INSTITUTE OF METALS (Swansea Local Section) (at Swansea University College), at 7.15.—General Discussion.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—A. P. Rale: Notes on *Methods of Producing Modern High Grade Machine Tools*.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (at Literary and Philosophical Society, Newcastle-on-Tyne), at 7.30.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. Gilbert Murray: The Beginnings of the Science of Language.

SATURDAY, MARCH 14.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: The Counting of the Atoms (III.).

PUBLIC LECTURES.

SATURDAY, MARCH 7.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Miss M. A. Murray: Modern Excavations in Egypt.

MONDAY, MARCH 9.

BEDFORD COLLEGE FOR WOMEN, at 5.15.—Prof. L. Lévy-Bruhl: Trois Philosophes français contemporains: Ribot, Espinas, Durkheim (in French) (Succeeding Lectures on March 10, 13.)

UNIVERSITY COLLEGE, at 5.30.—Prof. H. Westergaard: Vital Statistics. (Succeeding Lecture on March 11.)—Miss E. Jeffries Davis: Some Famous London Bridges (I.) (Succeeding Lectures, by Prof. A. E. Richardson, on March 16, 23.)

INNER TEMPLE HALL, at 3.—*Lord Newton*: The Necessity for Legislation with regard to Smoke Abatement (Chadwick Lecture).

TUESDAY, MARCH 10.

UNIVERSITY COLLEGE, at 5.30.—R. A. Smith: The Old Stone Age.

UNIVERSITY OF LEEDS, at 8.—E. Percival: The Freshwater Zoology of Yorkshire (I.).

WEDNESDAY, MARCH 11.

SCHOOL OF ORIENTAL STUDIES, at 5.15.—E. Richmond: Early Moslem Architecture. The Early Madrassas in Syria, Bagdad, Egypt up to end of Ayyubi Dynasty. Developments during the Mamluke Period up to the Turkish Conquest.

KING'S COLLEGE, at 5.30.—Prof. E. Prestage: Travel and Travellers of the Middle Ages (IX.). The Opening of the Ocean Routes, A.D. 1415–60.

UNIVERSITY COLLEGE, at 5.30.—Miss Ethel S. Fegan: Library Resources outside London.

THURSDAY, MARCH 12.

UNIVERSITY COLLEGE, at 5.—Prof. E. A. Gardner: History of Ancient Sculpture (Introductory Lecture).

SATURDAY, MARCH 14.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Dr. R. L. Sherlock: Man as a Geological Agent.

Supplement to NATURE

No. 2888 MARCH 7, 1925

Electric Forces and Quanta.[1]

By J. H. JEANS, Sec. R.S.

IT is just about twenty-five years since Lord Kelvin spoke of "two clouds" obscuring "the beauty and clearness of the dynamical theory which asserts light and heat to be two modes of motion." The clouds which Lord Kelvin saw as clouds no bigger than a man's hand have grown until they have almost filled the firmament: little can now be seen of the beauty and clearness of the dynamical theory of which Lord Kelvin spoke. The old dynamical theory has given place to the new theories of relativity and of quanta; what Lord Kelvin thought were transient clouds shortly to melt away have proved to be new theories in process of growth, the "beauty and clearness" he saw under these clouds was mostly a mirage.

I have chosen as my title "Electric Forces and Quanta," the two halves of this title corresponding roughly to the two new theories, and I propose to try to sketch out the changes these theories have introduced into our conception of fundamental electrical processes. Let us consider electric forces first. Lord Kelvin, following Maxwell and Faraday, regarded an electric force as evidence of a stress in the ether. An ether can transmit two kinds of stress, one arising from a state of static strain and the other from a transfer of momentum; these were supposed to be electric and magnetic forces respectively. Or, to put the matter in another way, an ether can possess two kinds of energy, potential and kinetic; these were identified with electrostatic and electromagnetic energy respectively. This mechanism of stresses in the ether was devised in order to escape the necessity of "action at a distance." The ether itself had no doubt originally been brought into existence for quite other reasons—to provide a nominative to the verb "to undulate," according to the late Lord Salisbury—but these other reasons were no longer of much cogency. Light, whether an undulation of a medium or not, was admittedly an electromagnetic phenomenon, and the electromagnetic theory of light had already made it clear that any mechanism which could account satisfactorily for electric and magnetic forces could carry the whole of the undulatory theory as well. It was because Maxwell and Faraday had disliked "action at a distance" that the ether continued in existence at the end of the nineteenth century.

A Medium or Action at a Distance

Nevertheless, the conception involved a difficulty which seems to have troubled the nineteenth-century physicists not a little. The energy of the ether could represent all kinds of electromagnetic energy, but could represent nothing else. Gravitational energy, for example, could not be interpreted as ethereal energy, for the only two types of energy which the ether could hold were already allotted to electric and magnetic energy respectively. It is true that attempts were made to interpret gravitation as normal waves of compression or as pulsations of very high frequency in the luminiferous ether, but such explanations never survived comparison with facts, and those who tried to explain gravitation had to fall back either on a new and entirely separate ether or else on action at a distance. If action at a distance had to be called in to explain gravitation, it might just as well be allowed to explain electromagnetism as well, there seemed to be no logical resting-place between two ethers and none. But the need for multiple ethers simultaneously filling space aroused suspicions in those who were conversant with the history of science. In an earlier century, according to Sir Joseph Larmor, "aethers were invented for the planets to swim in, to constitute electric atmospheres and magnetic effluvia, to convey sensations from one part of our bodies to another, and so on, till all space had been filled three or four times over with aethers. It is only when we remember the extensive and mischievous influence on science which hypotheses about aethers used formerly to exercise, that we can appreciate the horror of aethers which sober-minded men had during the eighteenth century."

In time it became clear that the only thoroughly satisfactory possibility was no ether at all. First the development of the theory of relativity gave its death-blow to the old luminiferous ether of Lord Kelvin, Maxwell, and Faraday. The main result of this theory can be stated in the form that all the phenomena of Nature go on precisely as though there were no ether.

[1] The Sixteenth Kelvin Lecture, delivered on February 5 at the Institution of Electrical Engineers.

This does not of course abolish the ether; it shows the conception of an ether to be superfluous and perhaps even a little bit ridiculous—for it is ridiculous to fill the whole of space with a medium and then agree that everything goes on just as if the medium were not there—but it does not show it to be illogical.

The Existence of an Ether.

To the question, "Does an ether exist?" science is still unable to give a definite answer. The question, "Does the ether exist?" if the ether is taken to mean the luminiferous ether of Maxwell and Faraday, ought almost certainly to be answered in the negative. Speaking for a moment in the language of technical mathematics, the reason is that all the phenomena of Nature are invariant to the Lorentzian transformation (the transformation to axes moving with a uniform velocity), whereas the physical properties allotted to the ether by Maxwell and Faraday are not invariant. Let E and H denote the electric and magnetic force at a point in the supposed ether, then E^2-H^2 (the integrand in the action integral) is invariant, so that all properties which follow from the principle of least action are independent of the motion of the observer. These are of course the dynamical properties of the system. But E^2+H^2 is not invariant, so that the phenomena which follow from attributing energy to the ether at a rate $(1/8\pi)(E^2+H^2)$ per unit volume are not the same for a moving observer as for a stationary one.

Of the six components of stress attributed by Maxwell to the ether, only three are invariant, so that electromagnetic phenomena, if explained in terms of ether stresses, call for stresses which are not the same for a moving observer as for one at rest even though the observed phenomena are absolutely identical. For example, if magnetic forces are of ethereal origin, then the forces observed by a moving observer must be of quite different nature and origin physically from those observed by an observer at rest. If the latter observer's forces are produced by Maxwell's mechanism, the former's cannot be. To take the simplest example: an observer moving through a stationary electrostatic field will in actual fact observe magnetic forces just as much as if the field moved past him, yet the ether at every point of his path possesses no kinetic energy and so, according to the Maxwell-Faraday conception, could show no magnetic forces. The old Maxwell-Faraday ether had in some way to provide a duplicate mechanism for a single phenomenon, the magnetic force arising from an electric charge—and similarly for most other phenomena. No one has ever shown that it is capable of doing this; but even if they had, the duplication of mechanism to produce a single phenomenon is so contrary to the usual workings of Nature that there is not much risk in dismissing the old ether to the lumber-room.

Thus we may be confident that if an ether exists, it must be something very different from the Maxwell-Faraday ether. It must probably be thought of as a four-dimensional structure and must be more subjective than the Maxwell-Faraday ether. Each of us must carry his own ether about with him, extending through all space and all time, much as in a shower of rain each observer carries his own rainbow about with him. Whether such a structure, if it exists, ought to be called an ether, others must decide.

We may remark in passing that the conception of an ether has always made a special appeal to the practical, one might almost say engineering, type of mind which we associate with the leaders of British science. While our own physicists have asked for Nature to be reduced to a machine transmitting tensions and stresses, the more metaphysical minds of the Continent have usually been content to accept action at a distance as an ultimate explanation of natural phenomena, or at least to regard such an explanation as being in every way as final and as satisfying as an explanation in terms of a medium. It was something more than a coincidence that Newton, Kelvin, Clerk Maxwell, and Faraday were all British, while Boscovitch, Einstein, and Weyl are not.

Four-dimensional Geometry.

The paper which practically abolished the ether as a serious scientific hypothesis was published by Einstein in 1905. Ten years later he published a second paper which may be said to have shown us how to get on without either an ether or action at a distance. His first paper, as afterwards interpreted by Minkowski, had shown that all the phenomena of electromagnetism might be thought of as occurring in a continuum of four dimensions—three dimensions of space and one of time—*in which it is impossible to separate the space from the time in any absolute manner*. You may separate them in one way, but you will find that I separate them differently, and in the end we shall both agree that no objective separation is possible.

Einstein's second paper showed that the phenomena of gravitation could be explained on the supposition that the geometry of this four-dimensional continuum was not of the ordinary Euclidean type. The continuum was supposed to be affected by kinks and twists in the neighbourhood of gravitating masses, and it was these, and not a "gravitational force," that threw a particle out of a straight course. It became just as inaccurate to say that the sun attracts the earth as to say that a bowl on an uneven bowling green is attracted or repelled by the other bowls. In this curved space

the path of a particle is always a geodesic—the most direct distance between two points—and this may have very different properties from a Euclidean straight line

We must, of course, remember that the paths we are discussing are in a four-dimensional space—if we were speaking of ordinary paths in three-dimensional space, it would clearly be ridiculous to say that the curved orbit of a planet provided the most direct path from perihelion to aphelion ; it is only when we allow for the motion in time as well as in space that the statement becomes reasonable We can get rid of most of the motion in time by supposing our planet, or other body, to move with enormously high velocity, and then the path described actually approximates to a straight line, which is now the most direct path even in three-dimensional space.

We can gain some conception of the main features of Einstein's geometry from the analogy of spherical geometry ; the curved surface of our earth provides a fair two-dimensional analogy to Einstein's curved four-dimensional space. To one who thinks in terms of "parallels" of latitude and longitude, or who studies geography on a Mercator chart, the most direct course on our earth's surface looks oddly curved : it is always a surprise to the unsophisticated traveller that the ship taking him from Southampton to New York (say from A to B in Fig. 1) turns a bit to the north on rounding the Lizard, while the great circle course on the ship's chart (AECB in Fig. 1) looks very much as if the ship were describing an orbit about a centre of attraction in the middle of the Sahara.

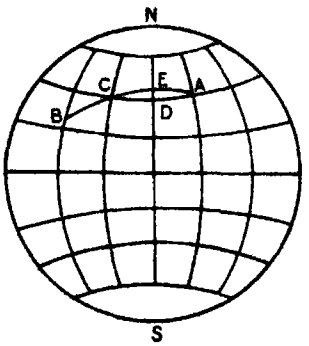

Fig. 1.

If Einstein was able to avoid the evils both of action at a distance and of an ether in the gravitational problem, there would seem to be no reason why they should not be similarly avoided in the electromagnetic problem which specially interests us to-night. Not only is there no reason why this should not be done ; it actually has been done. In 1918 Weyl pointed out that the geometry of Einstein was not the most general geometry which conformed to the relativity condition. Space could be distorted still further in ways unimagined by Einstein, these further distortions of the four-dimensional space being specified by the six components of a vector. Now the significant thing is this. On calculating the relations which must hold between the six components of the vector in order that the relativity condition may be satisfied, Weyl finds equations which are precisely identical with the electromagnetic equations of Maxwell, the six components in question now appearing as the three components of electric force and the three components of magnetic force.

Weyl's Electromagnetic Theory

It is not easy to explain in non-mathematical language what is the essential difference between Weyl's space and the old Euclidean space. We can best attempt it by treating Einstein's space as a half-way house. Returning for a moment to the two-dimensional analogy provided by the earth's curved surface, we know that the length of a degree of longitude decreases as we recede from the equator ; the ship turns north on its voyage from the Lizard to New York in order to take advantage of the shorter degrees of longitude up north. The planet going round the sun describes a curved path for a similar reason. According to Einstein's theory, a measuring rod changes in length as it moves about in a gravitational field—a two-foot rule is no longer two feet in length if taken from the earth to the sun ; it is because of this that the wave-length of the light represented by a definite spectral line when emitted at the sun's surface is different from that of the same light emitted on earth. The length of the rod depends only on its distance from the sun, being, in fact, proportional to

$$\left(1-\frac{2\gamma m}{rc^2}\right)^{-\frac{1}{2}},$$

where γ is the gravitation constant, m the mass of the sun, c the velocity of light, and r the distance from the sun. But in Weyl's space the length of such a rod does not depend solely on its position ; it depends also on the path by which this position has been attained. A rod of length l displaced parallel to itself through a distance dx, dy, dz, dt in the four-dimensional continuum may be supposed to experience a change of length dl defined by

$$dl = l(Fdx + Gdy + Hdz - \Psi dt),$$

where F, G, H, Ψ are quantities which need not at present be specified. If the rod is taken a journey from P to Q its whole change of length will be given by

$$\log \frac{l_q}{l_p} = \int_P^Q (Fdx + Gdy + Hdz - \Psi dt).$$

In Einstein's geometry the integrand is necessarily a perfect differential, so that the value of l_q/l_p depends only on the position of Q and P and not on the particular path selected from P to Q ; the condition that this integrand shall be a perfect differential is expressed by the six equations

$$\frac{\partial H}{\partial y}-\frac{\partial G}{\partial z}=0, \qquad -\frac{\partial \Psi}{\partial x}-\frac{\partial F}{\partial t}=0,$$
$$\frac{\partial F}{\partial z}-\frac{\partial H}{\partial x}=0, \qquad -\frac{\partial \Psi}{\partial y}-\frac{\partial G}{\partial t}=0,$$
$$\frac{\partial G}{\partial x}-\frac{\partial F}{\partial y}=0, \qquad -\frac{\partial \Psi}{\partial x}-\frac{\partial H}{\partial t}=0.$$

In Weyl's geometry, on the other hand, the integrand $Fdx+Gdy+Hdz-\Psi dt$ is not a perfect differential, so that the quantities on the left hand of the equations just written down do not vanish; they have values a, b, c, X, Y, Z different from zero, so that

$$\frac{\partial H}{\partial y}-\frac{\partial G}{\partial z}=a, \qquad -\frac{\partial \Psi}{\partial x}-\frac{\partial F}{\partial t}=X,$$
$$\frac{\partial F}{\partial z}-\frac{\partial H}{\partial x}=b, \qquad -\frac{\partial \Psi}{\partial y}-\frac{\partial G}{\partial t}=Y,$$
$$\frac{\partial G}{\partial x}-\frac{\partial F}{\partial y}=c, \qquad -\frac{\partial \Psi}{\partial z}-\frac{\partial H}{\partial t}=Z$$

These are precisely Maxwell's electromagnetic equations, F, G, H being the components of the magnetic vector potential, and Ψ the electrostatic potential. Turning back, we see that F, G, H, and Ψ are determined at any point by the rate at which a measuring rod of unit length changes its length as it passes through that point

When Einstein explained gravitation in terms of curvatures and special metric properties of space, the equations of his theory were found to be different from those of the old Newtonian theory. It was accordingly possible to make an observational test between the two theories, and this decided immediately and conclusively in favour of the theory of Einstein. There is no hope of establishing the truth of Weyl's theory in a similar way, for, as we have just seen, the equations to which it leads are precisely identical with the already universally accepted equations of Maxwell. Weyl's theory can only be judged by its inherent plausibility or the reverse.

Judged by this standard, everything seems to be in its favour. The luminiferous ether failed, partly because it left no room for gravitation, partly because its mechanism had to be supposed to be too elaborate for the facts to be explained The hypothesis of an ether led us to anticipate a whole series of different phenomena corresponding to different velocities through the ether, so that when these were not forthcoming, its advocates were compelled to elaborate a complicated theory by which all the forces of Nature were in collusion to make these different occurrences appear the same to us. The Einstein-Weyl geometrical theory escapes both these reproaches Both gravitation and electromagnetism fit perfectly naturally into their places. These two systems of forces correspond exactly and completely to the ways in which a four-dimensional geometry can differ from the simple geometry of Euclid. The observed forces of gravitation and electromagnetism correspond exactly to the most general forces which are possible, if "force" is interpreted simply as an illusion arising from a crumpling up of space. Consequently the observed phenomena of Nature are precisely those which ought to be observed —not one is missing and neither is there room for a single one more. There is now no collusion among the forces of Nature to conceal a whole series of unobserved phenomena: indeed, there could be no concealment because there is nothing to conceal. By its simplicity, its completeness, and its perfect agreement with the observed phenomena of Nature, the theory seems likely to take its place as our final interpretation of the "forces" of Nature.

We now see that the universe of Euclid, in which parallel lines never meet and in which two sides of a triangle are always greater than the third, was a simplified ideal universe. In the same way the universe of Aristotle and Plato, in which space and time are permanently distinct and essentially different in their natures, was a simplified ideal universe. Both universes were too simple to fit the facts, remove the unwarranted simplifications and we are left with a universe the geometrical properties of which are expressed by such equations as Einstein's gravitational equations (to which Newton's inverse square law gives a good approximation) and Maxwell's electrodynamical equations. Thus geometry, cleared of *all* unjustifiable assumptions, transforms itself into mechanics, both gravitational and electrodynamical A being who was born without any one of his five senses, but with unlimited geometrical reasoning powers, could deduce the general nature of the actual world without any experience of reality: he would anticipate that landslides, earthquakes, thunderstorms, and auroræ would occur, but he would know nothing about "forces," and would regard these phenomena merely as geometrical necessities.

Atomicity.

Although generalised geometry can predict and explain all the systems of forces of the universe, it has its limitations; there are features of the actual universe before which it stands powerless. Nothing in geometry can explain the essential differences between positive and negative electricity, or the atomicity of electric charges, so that the whole inner structure of matter, including the whole of chemistry, would be outside the scope of the intuitions of our supposed geometer.

Electric charges are a consequence of, or at least are associated with, a curving or crumpling of space, but so far as pure geometry goes there is no restriction on the extent of this crumpling, so that our geometer, reasoning from geometry alone, might expect to find charges of all possible amounts, whereas in actual fact

electric charges occur only in multiples of a definite unit, the charge of an electron. It is clear, then, that there is something more than geometry underlying the phenomena of Nature; the whole phenomenal universe may be geometry with restrictions if we like, but not merely the geometry which is obtained by generalising the geometry of Euclid until we can generalise no further. Space can be crumpled up qualitatively in all the ways known to geometry but not quantitatively; the uniformity of the electronic charge must in some way represent an absolute restriction on the measure of the crumpling.

Each particle of matter—each electron, let us say—occupies one point of space at any one instant of time, and the succession of these points will form a line in the four-dimensional space-time continuum—the "world-line" of the electron. In the neighbourhood of this world-line there is a deformation of the continuum due to the existence of the electron.

The near approach of two electrons or of any two charged particles is represented by a near approach of their world-lines in the four-dimensional continuum. Each world-line is surrounded by its associated deformation, and in regions in which the world-lines are near to one another the adjacent regions of the continuum will be doubly deformed.

A priori there are two possibilities open The first is that the two deformations are merely additive, just as, when two ships approach, each making its own wash (or deformation of the surface of the sea), the height of wash at any point is the sum of the heights of the washes made by the two ships independently. The second possibility is that, as there have been found to be restrictions on the amount of deformation associated with the two separate world-lines, there may be a further restriction on the deformation arising from their combination.

In actual fact the former alternative appears to prevail when one or both of the charged particles are "free" electrons, but the latter alternative when they are "bound" together; that is, when they are permanently describing orbits about one another. It is these latter restrictions that have given rise to the theory of quanta. Just as the restrictions associated with single world-lines give rise to an atomic constant e, the charge on an electron, so the restrictions associated with pairs of world-lines give rise to a second atomic constant. This is generally taken to be h, Planck's constant, but in many respects it is more appropriate to regard the product hC as the second constant, where C is the velocity of light. It is significant that hC is of the same physical dimensions as e^2 and so may be regarded as being the same thing as e^2 except for a numerical multiplier. Thus while the restrictions connected with one world-line introduce e, those connected with two world-lines, depending only on e^2, introduce no essentially new constant, whence it may reasonably be suspected that the two sets of restrictions are merely different aspects of one and the same set. It looks as though the atomicity of the quantum theory is only another aspect of the atomicity of electric charges.

Quantum Restrictions

We can perhaps best visualise the inner nature of the quantum-restrictions by going back to the analogy of the two ships making a combined wash which is in some way restricted to being of a certain height We have supposed each wash individually to be restricted; if the velocity of the ships is fixed, this requires that each ship shall be of a definite size (corresponding to each electron having a definite charge). How can we now put a further restriction on the total wash of the two ships at points where their washes overlap? Only, I think, by keeping the ships at a specified distance apart. At any rate this is the way in which the quantum-restrictions work. The normal hydrogen atom consists of a negative electron describing a circular orbit about a positively charged nucleus; the quantum-restrictions compel this orbit to keep an unvarying radius of $0{\cdot}53 \times 10^{-8}$ cm. When the atom is in an abnormal state, as, for example, when excited in a vacuum tube, the orbit, if circular, may have radii equal to 4, 9, 16, 25 . . times the radius of the normal atom Elliptic orbits also are possible, but only of quite definitely restricted major and minor axes. In actual fact the semi-major axis must be equal to one of the radii permissible for a circular orbit, while the ratio of the two axes must be one of a range of commensurable ratios. The orbits which are possible for the electron of the hydrogen atom are shown in Fig. 2. If it were not for the quantum restrictions, it would be impossible to exhibit these orbits in a diagram at all; orbits of every radius and of every eccentricity would be possible, just as they are for a planet or comet describing an orbit about the sun.

It will be understood that I have not approached the quantum theory by the road of its historical development. Planck originally discovered the existence of the quantum-constant h from a study of black-body radiation. The famous theorem of equipartition of energy showed that if the classical laws of dynamics were of universal validity, the whole energy of the material universe would at once degrade itself into radiant energy of infinitesimal wave-length. Planck showed that this conclusion could be avoided by supposing that the energy of radiating mechanisms changed only by complete quanta, the change of energy $W_2 - W_1$

being connected with the frequency ν of the radiator by the relation

$$W_2 - W_1 = h\nu.$$

He further showed that this supposition led to a law of spectral distribution of black-body radiation, the now famous Planck's law, which was found to agree excellently with the observed distribution. In this way the quantum theory came into being at the very beginning of the quarter-century we have under review.

Some years elapsed before Einstein showed that the same constant was of fundamental importance in the photo-electric effect, and it then began to be suspected that it might conceivably be fundamental to the whole of physics But it was not until 1913 that Bohr published the epoch-making paper which first suggested, and at the same time finally established, that this

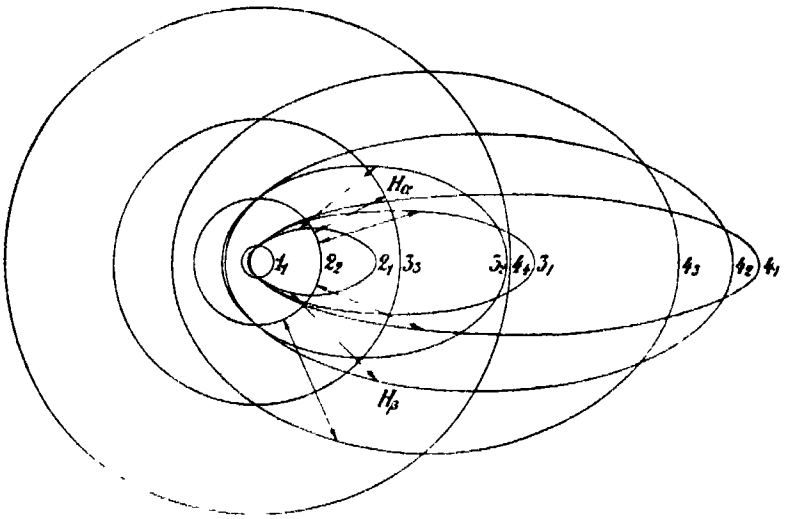

FIG. 2

constant held the clue to the structure of the atom and determined the scale on which the universe is built. To-night I have disregarded historical development altogether, and have tried to approach the theory in the simplest manner, I am trying to make it look natural. There can be no reasonable doubt that the quantum theory is essentially true, and so would appear perfectly natural to us if we could approach it with entirely fresh minds not already obsessed by erroneous ideas. But with our minds such as they are, the quantum theory as frequently presented does, it must be admitted, raise recollections of plausible conjuring performances If I were to state the argument by which Planck first arrived at the existence of the quantum, the inclination might well be to dismiss it as mere mathematical sleight-of-hand I agree it is still a bit surprising that the rabbit came out of the hat, but I have tried to show at least that there was so much room in the hat that almost anything might have emerged.

According to the Maxwellian electrodynamics an electron describing an orbit of any kind must necessarily radiate energy. We can calculate the rate at which energy ought to be radiated by the electron in the normal hydrogen atom; it is 0·46 erg a second. The resulting loss of energy would be compensated by a decrease in the radius of the orbit; we find that the rate of this decrease would be about 112 cm. a second, so that the atom ought to disappear altogether within a small fraction of a millionth of a second Thus it is the quantum-restrictions which give a permanent existence to matter

In conformity with the quantum-restrictions, the electron in the hydrogen atom describes an orbit of unvarying radius and so of constant energy. Maxwell's equations, as we have seen, would demand that radiation should be emitted and that the energy of the orbit should decrease accordingly. Here, then, we have a case where the requirements of Maxwell's theory and those of the quantum theory are in irreconcilable conflict It is the quantum theory which carries the day. Somewhere before we reach the most minute of all structures, Maxwell's theory fails and the quantum theory takes its place. For large scale phenomena the two theories coincide — a thunderstorm is the same thing for Maxwell's theory as for the quantum theory, just as it was the same thing for the old "one-fluid" theory as for the modern electron theory—atomicity is of no consequence when the number of atoms involved approximates to infinity.

In terms of space curvatures we may say that Maxwell's theory is represented by a continuous curvature or crumpling such as might be applied to a rubber membrane, while possibly the quantum theory may be represented by a so-to-speak "jerky" deformation which is the best that can be done with a scaly surface such as a crocodile skin. If we wish to cover the earth's surface with a membrane, it makes little difference, from the point of view of closeness of fit, whether we select rubber membrane or crocodile skin, but it makes all the difference if we are manufacturing a pair of gloves. The quantum theory represents, perhaps, a quality of space, or rather of the four-dimensional continuum, which is somehow analogous to scaliness in a skin.

As the normal hydrogen atom is already in its configuration of minimum energy it can emit no radiation. But under electric bombardment or in the presence of intense radiation, the electron may move to other orbits of energy higher than the minimum. Even now there can be no gradual change of energy, but there can

be spasmodic jumps from one orbit to another orbit of lower energy. According to Bohr's theory of atomic mechanism, the energy lost to the orbit at each one of these jumps is emitted in the form of monochromatic radiation. A jump from energy W_2 to energy W_1 results in the emission of radiation of uniform frequency ν where

$$W_2 - W_1 = h\nu,$$

h being the absolute constant of Nature already referred to. If λ is the wave-length of the radiation, $\lambda = C/\nu$, so that

$$W_2 - W_1 = \frac{hC}{\lambda}$$

We have already seen that hC is equal to Ke^2 where K is a numerical constant. The energy in an orbit of radius r (or, if elliptical, of semi-major-axis r) is $-\frac{1}{2}e^2/r$, so that if the jump is from an orbit of radius r_1 to one of radius r_2,

$$\tfrac{1}{2}e^2\left(\frac{1}{r_2} - \frac{1}{r_1}\right) = \frac{Ke^2}{\lambda},$$

and the wave-length of the radiation is given by

$$\frac{2K}{\lambda} = \frac{1}{r_2} - \frac{1}{r_1}.$$

Now if a is the radius of the normal hydrogen atom, the possible values for r_2 and r_1 are 1^2, 2^2, 3^2, 4^2 . . . times a, so that our formula becomes

$$\frac{2Ka}{\lambda} = \frac{1}{n_2^2} - \frac{1}{n_1^2}.$$

In actual fact a formula of this type, in which n_1 and n_2 are given all possible integral values, is found to give with the utmost exactness the wave-lengths of the light emitted in the complicated spectrum of the hydrogen atom. On putting $n_2 = 2$ we obtain the Balmer series of lines, of which the principal lines H_α, H_β, H_γ . . . form the most conspicuous feature in the ordinary hydrogen spectrum. The lines obtained by putting $n_2 = 1, 3, 4, 5$ . . . are mostly in the infra-red or the ultra-violet. Many of these have been observed, and there is no reason to doubt that the remainder are there, although at present beyond the range of observation.

So far we have considered only the circular orbits; there must, of course, be other spectral lines arising out of the possibility of the electron describing elliptic orbits. Exact analysis shows, however, that these latter lines coincide almost exactly with those already discussed. They would coincide perfectly if it were not that the mass of a moving electron depends on the velocity of its motion. As a consequence of this dependence of mass on velocity, the two sets of lines do not exactly coincide. Each line of the simple series previously discussed is replaced by a "fine-structure" —a bunch of lines quite distinct in fact, although so close together as to look like a single line in all save the most powerful spectroscopes. Sommerfeld has worked out the structure to be expected theoretically for these bundles of lines and obtains a most gratifying agreement with observation. This and other experimental tests give the most convincing proof of the accuracy of Bohr's theories of atomic mechanism.

We can gain a knowledge of the arrangements of the electron orbits in even the most complicated atoms by using the equation

$$W_2 - W_1 = h\nu,$$

which appears to be of universal validity. The frequencies ν of radiation can be measured, so that the energy-levels W_1, W_2 . . of the various possible orbits can be calculated. The method has been applied not only to discovering the arrangements of electrons in the atom, but also to discovering the energy-levels of the protons in the nucleus. At present the hydrogen atom and the positively-charged helium atom are the only structures which are completely understood, but there can be little doubt that in time the method will unravel for us the secrets of even the most complicated of atomic and molecular structures

Already Bohr has constructed a table, of which the first part is shown in Table I, in which he attempts to assign the different electrons in the atoms to the

various orbits permitted to them by the quantum theory. The numbers in the top line specify the orbits in terms of their principal and subsidiary quantum numbers. The numbers below are the numbers of electrons which follow one another round in these different orbits. It will be noticed that in the simpler elements there are never more than four electrons in the same orbit, although in the heavier elements six and afterwards eight electrons may inhabit the same orbit. The table is largely conjectural, but recent spectroscopic research has gone far towards establishing its essential accuracy When we remember that it is less than twelve years since Bohr first suggested that the quantum theory might provide the clue to the structure of matter, we must agree that the progress of the theory in these years has been remarkable.

The Nature of Radiation.

The quantum theory has been less successful in discovering the nature of radiation, although even here it has been beyond comparison more successful than any previous theory. To illustrate the difficulties of the problem, let us consider one single phenomenon—the X-ray photo-electric effect. A thin stream of electrons each moving with the same high velocity is allowed to impinge on a material target, and X-rays are emitted which carry off the energy destroyed by the collision These X-rays pass through a gas, and it is found that as soon as the process starts, atoms are ionised and shoot off electrons with a velocity equal to that of the original stream of electrons. Even if the density of X-radiation is so slight that, according to the old view of radiation, an atom would take years to absorb the energy necessary for ionisation, nevertheless ionisation is found to begin at once, energy being absorbed which is not only sufficient for mere ionisation, but also suffices in addition to endow the ejected electron with high velocity.

Such a phenomenon is of course totally inexplicable in terms of the luminiferous ether, or even in terms of Maxwell's equations. The quantum theory gives only a partial explanation. Since the frequency ν of the X-rays does not change with their passage through space, the equation $W_2 - W_1 = h\nu$ shows that the change of energy at the one end of the chain must be equal to that at the other. Thus as much energy is necessarily yielded up to one electron as is destroyed in another, but this does not touch the problem of the mechanism by which this energy is transferred.

Einstein at one time suggested that radiant energy was hurled through space tied up in indivisible packets like bullets from a rifle, but it has proved quite impossible to reconcile this suggestion with the optical phenomena of interference. A more recent hypothesis, also due to Einstein, calls for a revision of our conception of the action of an electric field on an electron.

According to the usual electrical theory, an electric force X acting on an electron of charge e and mass m for a time t produces a change of velocity equal to

$$\frac{Xet}{m}.$$

According to Einstein's recent theory of radiation, this is only true if X arises from a steady field or from a field which changes infinitely slowly. A force X which results from the incidence of radiation will in general produce no change of velocity at all in an electron. Indeed a bound electron is compelled to describe a fixed orbit with a prescribed velocity which cannot change, while a quite simple argument shows that it would be contrary to the fundamental equation of the quantum theory for a free electron to have its velocity changed by radiation. Einstein, following Bohr, supposes that under certain conditions a bound electron can have its velocity changed by a definite amount Q. This amount is not equal to Xet/m, but is determined by the position and motion of the electron in the atom to which it belongs; Q must be such as to move the electron into a new orbit which is also one of the permitted few. The chance of such a jump of velocity occurring is supposed to be

$$\frac{(Xet/m)}{Q}$$

This conception immediately explains the otherwise incomprehensible photo-electric effect as well as other puzzles in the behaviour of radiation. The difference between a strong and a weak electric field acting on an electron is no longer that the strong field produces a big change of velocity and the weak field a small one; it is that the strong field has a big chance of producing a change, and the weak field only a small chance of producing the same change. When radiation acts on a body containing a great number of electrons, the final result is the same on the new theory as on the old. But there is a difference of method which is similar to the difference in propulsion between a motor-car and a steam-engine; on the new theory the charged body is propelled by a succession of little kicks, whereas on the old theory it was propelled by a steady pressure.

I have tried to sketch the outlines of the changes which the past quarter-century has introduced into our conception of the nature of electric forces and of the electromagnetic field. You will agree with me that there have been giants at work in the field of pure electrical theory. When the history of present-day science comes to be finally written, the quarter-century we have just lived through will, so far as we can now judge, stand out as the period in which man first began to understand the true nature of electricity.

Oceanic Research.

In his presidential address to the British Association at the Cardiff meeting of 1920, the late Sir William Herdman suggested that the time had come for a new deep-sea expedition on the scale of the *Challenger* voyage of 1872–74. This proposal was discussed at various Association meetings; a tentative scheme was approved and was then submitted for the consideration of other scientific bodies. The time, however, was regarded as inopportune and the proposal was not taken up. Now, it appears, the movement may come from the United States.

In 1923, Dr. H. C. Hayes, of the U S Navy, developed a very ingenious method of taking almost continuous ocean soundings by means of a sound-wave transmitted to, and reflected back from, the sea bottom This "echo-sounding" presented such possibilities for oceanographic surveys that definite suggestions were made for a national expedition, and, after considering these, Col. Theodore Roosevelt, the Acting Secretary of the U.S. Navy, summoned a meeting of representatives of government departments and extra-governmental establishments. This was held in July 1924, and was addressed by the Hon. Curtis D. Wilbur, Secretary of the Navy. A committee then prepared a report, which was adopted by the conference and sent to the Secretary.

The report recommends that a vessel, with officers and crew, should be supplied by the Navy. A scientific staff, consisting of an oceanographer, a biologist, and a geologist—all men of outstanding attainments—with six or more scientific assistants, will, it is expected, be provided from sources other than government funds. The cost of the first year's work, apart from the maintenance of the vessel and the salaries of the scientific staff, is estimated at about 57,000 dollars. How long the expedition will be away is not considered, but it is contemplated that a naval vessel will be permanently employed on oceanographic research.

The problems upon which the expedition is expected to concentrate are briefly outlined—they constitute a programme which is new, in some ways, and particularly attractive. The work of the *Challenger* was very comprehensive, but, in the main, it was biological in its attitude. Now, since 1872, the science of geophysics has been developed, and more attention is being directed to the morphology of the ocean floor. Existing oceanic soundings are so few that they are of little use in detailed studies, and so the method of finding the depth by echo-sounding must be largely used in any new oceanic expedition. During the last twenty years or so, a very extensive investigation into the subject of isostatic compensation in the earth's crust has been made by

the U.S. Coast and Geodetic Survey. The work accomplished has, however, been practically restricted to the North American continent, and its extension to the ocean floor and the deeps is most desirable.

Other geophysical problems demand close observations of the precise forms and positions of the deeps—the question, for example, of the downward warping of the ocean floor along the continental margins suggests the need for great numbers of new soundings in all regions. Evidence of submarine upheavals and dislocations, and of the occurrence and frequency of submarine earthquakes and volcanic eruptions, is urgently needed. There is necessity for a renewed investigation of the deposits on the ocean floor. Determinations of mean ocean depth in chosen places are needed Oceanic tides have scarcely at all been investigated, and even ocean currents are not so well known as they ought to be. The forms, heights, and velocities of ocean waves also require study.

Further, the great development of radio-telegraphy and telephony has suggested problems for which a much extended knowledge of electrostatic and electromagnetic fields in the atmosphere is required. Since the ocean covers five-sevenths of the earth's surface, most of this kind of investigation must be undertaken at sea The distribution of icebergs on the margins of steamship routes is already being studied by the U.S. Government, but a great extension of the field of investigation is necessary. Now, in addition to all these subjects of investigation, there are, of course, the routine physical and biological methods of research into the ocean water itself and the fauna of the sea floor. This would be done as a matter of course, but it is very interesting to see how "up-to-date" in its attitude to growing science is the programme for this new expedition.

It is recommended that the area of investigation should (at first) be the Gulf of Mexico and the Caribbean Sea. Then the research is intended to spread through the Panama Canal and to take in the North Pacific on one hand, and the North Atlantic on the other. At the present time oceanographic investigation of the Pacific Ocean is by far the most attractive side of the subject. There we obviously have ocean basins and continental margins *in the process of making* (for in the greater part of the Atlantic something like stability has been reached, and the problems there centre round sedimentation on the region of the continental shelf). A geophysical expedition dealing with the oceanic part of the earth's surface (for that is evidently what the present trend of scientific discovery suggests) cannot afford to concentrate on any relatively small part of the Pacific and Atlantic areas—the whole of the former region requires multitudes of ocean soundings at the very least. If, then, this big American expedition begins work very soon (and there is every likelihood that it will do so), the question of co-operation ought to be considered: it is a pity that such action was not discussed, and proposals of some kind made, at the conference.

At all events, the time is ripe for a consideration of the position of oceanographical investigation by Great Britain and other countries. For a long period now the objects of deep-sea expeditions have been very much the same as those of the *Challenger*—that is, the study of abyssal and pelagic ocean life, with the investigation of the physical conditions that influence the distribution and density of faunas and floras. Since the beginning of the work of the International Council for the Exploration of the Sea, oceanic research has had a strong fisheries bias, and, at the present time, a great deal of such investigation is actually in progress in the north European region: this is likely to develop still further its utilitarian and fishery objects, and its interest tends to become a very specialised and even an administrative one. We plead here for an interest which is much wider and should be purely scientific. During the last twenty years or so (and largely because of the original work of the International Council) oceanographic physico-chemical methods have been well developed. Hydrodynamical methods, on the mathematical side, are remarkably well developed and are far ahead of the observational side of the science. This is also the case with theoretical geophysical research: it waits for a sound and very extensive basis of observations, and that cannot be given by any amount of geological work on the land, for research on the five-sevenths of earth surface that is occupied by the ocean is urgently required.

Every consideration points, therefore, to deep-sea investigation on rather new lines, and the progress of geophysical and hydrodynamical research on one hand, and of oceanic meteorology on the other, suggest what these new directions ought to be. Now that a lead has been given by the proposed American naval expedition, it would be very gratifying if a similar British naval one could be planned out, and if it could be arranged that a large measure of co-operation of aims and methods were secured. In spite of all that has been done in Great Britain on fishery investigation, it is nevertheless true that scientific oceanography has been neglected ever since the time of the *Challenger* expedition, and we cannot see any reason why a small fraction of the resources and interests of our Admiralty should not be directed to the prosecution of pure oceanic research without a necessary utilitarian object.

Scientific Exploration in the Karakorum Mountains.

Paesi e Genti del Caracorum: Vita di Carovana nel Tibet Occidentale. By Giotto Dainelli. (Pubblicato sotto gli auspici della R. Società Geografica Italiana.) Vol. 1. Pp. viii+291+74 plates. Vol. 2. Pp. iv+323+95 plates. (Firenze: Luigi Pampaloni, 1924.) 120 lire.

THE Karakorum Mountains are of special interest, as they contain the greatest glaciers known outside the polar regions and Mt. Godwin-Austen, or K.2, the third highest summit of the Himalaya. Scientific knowledge of the country has been collected by many distinguished explorers, including the brothers Schlagintweit in 1854–6, Godwin-Austen in 1860–1, Sir Francis Younghusband in 1887, and Sir Martin Conway, who in 1892 traversed the full length of the three longest glaciers and mapped them. In 1913–14 the country was visited by an Italian expedition under Dr. Filippo de Filippi, who had accompanied the Duke of Abruzzi on his expeditions to the same region and East Africa. When de Filippi received the medal of the Royal Geographical Society for his share in these explorations, the two Asiatic expeditions with which he was concerned were described by Sir Francis Younghusband as the best led and scientifically equipped expeditions which had up to then worked in the Trans-Himalaya. The full narrative of the expedition will be given in a promised monograph by de Filippi. The present work consists of the journals of its geologist, Dr. Giotto Dainelli, and it records his personal experiences and observations. He is well known from his work in East Africa, reminiscences of which lead to his contrasts between the modest simplicity of African caravans and the large cavalcade and numerous companies of coolies of Asiatic expeditions. The work also expresses the fascination of this country as compared with tropical Africa, owing to the more advanced architecture, culture, and religious development.

The two volumes tell the story of the journey from Marseilles to Bombay, and thence through Kashmir and by the well-known road across the Himalaya by the Zogi La to Dras and to the Indus at Tolti and Skardu. Thence Dr. Dainelli made a series of expeditions through the Karakorum valleys. He reached the ends of the Baltoro and Biafo glaciers, which were surveyed by Sir Martin Conway. The nearest comparable height among the glacial endings given is that of the Biafo, which Dainelli puts at 10,049 ft. and Sir Martin Conway determined as 10,120 ft., so there had been no material movement of the end of that glacier in the intervening twenty years. Dr. Dainelli did no serious mountaineering in this district and Sir Martin Conway's maps of the glaciers are incorporated in the author's general map. Later on, in the north-eastern Karakorums, Dr. Dainelli explored some less-known regions, including the Rimu Glacier, one of the sources of the Yarkand River, and there the expedition added materially to geographical knowledge. After many journeys in the valleys south of the main glacial region of the Central Karakorums, the expedition proceeded to Leh. Dr. Dainelli shows the charm of that country by many photographs of the picturesquely placed monasteries or gompas, and his descriptions of the religious dances.

From Leh the expedition proceeded north-westward to Depsang, on part of the way using yak, which the author describes as the camel of the mountain deserts. He visited some little-known valleys, and, among other features of interest, various hot springs and salt lakes. In this district Dr. Dainelli crossed the routes of the Schlagintweits, whose work he praises highly, though in parts of this country the latest Indian map was so sketchy that he could not determine his place on it. From Depsang he explored the Ciong Cumdan and Rimu Glaciers, with their interesting moraines, glacial lakes, and stratified ice. Thence following the Yarkand River, the expedition descended, with obvious regret, from the mountains to the monotonous steppes of Turkistan. During the return journey the explorers were arrested at Moscow as German spies, but promptly released on the intervention of the Italian Ambassador; they proceeded through Petrograd and Stockholm to Berlin, which the author describes as in October 1914 apparently following its normal life.

The two volumes of Dr. Dainelli's experiences give an interesting account of the conditions under which the work of the Filippi Expedition was conducted and show what great opportunities its members enjoyed. The author describes the work as a faithful journal of his share in the expedition, and it gives useful observations on the topography and people Its value as a work of reference is much lessened by the absence of an index, which would be especially useful where the spellings in the text and map differ, as in Olang and Olting. The expedition worked near an area of special interest in reference to the structure of Central Asia. The observations of this expedition may resolve the different interpretations of the Mustag-ata which, according to Suess, is a transverse meridional chain breaking unexpectedly across the main trend of the Asiatic ranges. This conclusion was rejected by the late Sir H. H. Hayden, who did not, however, fully explain the facts of which Suess's view was offered as an interpretation. There is but little information on these questions in the journal, though the expedition obviously collected much new material. Dr. Dainelli remarks, for example, that the Museum of San Marco

would not have space to hold their collections of fossils; but as to what the fossils are we must wait for the later monographs. Similarly, the rocks are often graphically described; but they are not identified, and the picturesque pinnacles and masses of limestone shown in the photographs are of unstated age.

The technical work of the expedition is being published in 13 parts, dealing with the geology, geography, palæontology, petrology, ethnology, botany, zoology, and geodesy. The only report yet issued is that on the glaciers, a volume with a fine atlas by Dr. Dainelli. His journal is illustrated by numerous beautiful photographs and a four-sheet topographic map on the scale of 1-750,000, which is a valuable addition to the geography of the central and north-eastern Karakorums. J. W. G

Studies in the History of Medicine.

(1) *Essays on the History of Medicine.* Presented to Karl Sudhoff on the occasion of his Seventieth Birthday, November 26, 1923, by Sir T. Clifford Allbutt, Arturo Castiglioni, Friedrich Dannemann, Paul Diepgen, Erich Ebstein, Fielding H. Garrison, Ernst Howald, Arnold C. Klebs, E. O von Lippmann, Max Neuburger, Sir Humphry Rolleston, Henry E. Sigerist, Charles and Dorothea Singer, W G. Spencer, Georg Sticker, E. C. Streeter, Lynn Thorndike, G. A. Wehrli, and Edward Theodore Withington. Edited by Charles Singer and Henry E. Sigerist. Pp. v+418+24 plates. (London: Oxford University Press; Zurich: Verlag Seldwyla, 1924.) 42*s.* net.

(2) *The Doctor's Oath: an Essay in the History of Medicine.* By W H. S. Jones. Pp. vi+62. (Cambridge: At the University Press, 1924.) 7*s.* 6*d.* net.

(3) *A Pioneer of Public Health—William Thompson Sedgwick.* By E. O. Jordan, G. C. Whipple, and C.-E. A. Winslow. Pp. xvi+193+5 plates. (New Haven: Yale University Press; London: Oxford University Press, 1924.) 18*s.* 6*d.* net.

(1) THE *Festschrift* dedicated to Prof. Karl Sudhoff on the occasion of his seventieth birthday consists of eighteen essays contributed by writers from England, the United States, Germany, Austria, Switzerland, and Italy. The essays, eight of which are in English, nine in German, and one in Italian, have been classified by the editors into the five groups of antiquity, Middle Ages, Renaissance, modern times, and general subjects respectively.

The first group contains essays on prehistorical attempts to prevent and stamp out epidemic disease, by Dr. Georg Sticker of Würzburg, the work of Philolaus, by Dr. Ernst Howald of Zurich, and the scientific treatises ascribed to Theophrastus, by Dr. Lynn Thorndike of Cleveland. In the section devoted to the Middle Ages, Dr. E. O. von Lippmann of Halle writes on the history of alchemy; Dr. Diepgen of Freiburg discusses the influence of the Middle Ages on the progress of medicine; Dr. and Mrs. Singer deal with the origin of the medical school of Salerno, which they show to be the result of combined Greek, Latin, Jewish, and Saracen influences; Dr. E. T. Withington gives an account of Roger Bacon's work entitled "On the Errors of Physicians"; and Prof. Arturo Castiglioni devotes an illustrated article to blood-letting in the arms of the Manfiedi, lords of Faenza. The third section contains papers by Dr. Henry E. Sigerist of Zurich on the birth of Western medicine; fifteenth-century miniatures of extra-mural dissection by Dr. E. C. Streeter of Harvard and Dr. Charles Singer; the "Practica of Gianmatteo Ferrari da Gradi, editio princeps," by Dr. Arnold C. Klebs of Noyon; and the "Epitome" of Vesalius on vellum in the British Museum, by Mr. W. G. Spencer.

Modern times are represented by contributions from Sir Humphry Rolleston on the reception of Harvey's doctrine of the circulation of the blood in England as exhibited in the writings of two contemporaries, namely, Thomas Winston (1575–1655) and Henry Power (1623–1668); from Colonel Fielding Garrison, on the newer epidemiology; and from Dr. Erich Ebstein of Leipzig on Frank Joseph Gall. The last group contains papers by Prof. Max Neuburger of Vienna on the history of the problem of Nature healing, parallelism in the development of the natural sciences and therapeutics, by Dr. F. Dannemann of Bonn, and the essence of folk medicine and the necessity for its historical study, by Dr. G. A. Wehrli of Zurich.

A bibliography of Prof. Sudhoff's works on the history of medicine, compiled by Dr. Sigerist, is appended.

No higher praise can be given to the volume than by saying that it is worthy of its recipient, whose services to the history of medicine are gracefully acknowledged in the preface by Sir Clifford Allbutt. The work is well printed, and accompanied by numerous excellent illustrations.

(2) Mr. W. H. S. Jones's scholarly work on the Doctor's Oath will interest alike the historian of ethics and the medical practitioner, inasmuch as medical ethics and the medical etiquette of the present day are based upon this famous oath.

After a brief account of the manuscripts of the Hippocratic collection, with an enumeration of the best manuscripts containing the oath, the Greek text of the Pagan Oath is given, with the English translation and critical footnotes. The chief variants in the later manuscripts are noticed, and are followed by a full

transcription of the Milan manuscript Ambrosianus B 113, which contains both the pagan and the Christian oath. The Greek text of the Christian modification of the oath, which in two manuscripts is written in the form of a cross, differs from the pagan oath in its omission of (1) reference to the pagan deities, (2) of all clauses in which preferential treatment is promised "to my teacher, his sons, my sons, and to those who have sworn allegiance to the physician's law," and (3) reference to a reward for instruction.

The Arabic text is also reproduced, as well as two Latin translations ascribed to N Perotti and Nicholas of Regium respectively.

In the subsequent commentary Mr. Jones points out that though the first certain reference to the oath is in the preface to Scribonius Largus, who flourished in the reign of Claudius, there is a possible allusion to it in the *Thesmophoriazusæ* of Aristophanes, *i.e.* as early as 400 B.C. The two versions of the oath, pagan and Christian, and their variants, suggest that the document had a wide circulation. The extant evidence does not conclusively prove that the oath was ever actually administered, and Mr. Jones suggests that it was "a counsel of perfection expressed in the form of an oath, just as many sepulchral epigrams in the Greek anthology are literary efforts which have never appeared on tombs."

In an appendix Mr. Jones compares the oath with the addresses to medical students in the old medical books of India, and reproduces the oaths still in use at the Faculties of Medicine at Montpellier and Glasgow.

(3) The memoir on the late Prof. William Thompson Sedgwick, who has been called the "Father of Epidemiology in the United States," consists of a series of essays by his former pupils, Prof. E. O. Jordan, G. C. Whipple, and C.-E. A. Winslow, preceded by an introduction by Prof. Sedgwick's widow. In the first essay, which deals with the public health movement in the 'seventies, the writers, after acknowledging the indebtedness of the United States to British sanitary science, point out that public health in the 'seventies was almost wholly concerned with the problems of the non-living environment. During Sedgwick's lifetime the public health movement assumed a biological character as the result of Pasteur's researches, and the way was laid open for the development of bacteriology and immunology.

In the succeeding essay, which is entitled "The Gate of Knowledge," an account is given of Sedgwick's early life. Though he registered as a medical student he never qualified as a medical practitioner, but devoted his whole career to biology, epidemiology, and public work. His most important achievement in the field of public health, of which an account is given in the following essays, was his investigation of a series of typhoid epidemics in 1894 which occurred in Massachusetts. His next most important contribution to public health science was the development of laboratory methods for the study of the microbiology of air, water, ice, and milk. He also paid much attention to the subject of food sanitation and conservation, and laid stress on the importance of statistics in epidemiology and of sanitary engineering, chemistry, and biology in the prevention of the chief communicable diseases.

Finally, Sedgwick was well known as a lecturer in subjects relating to public health not only in the United States but also in Great Britain, where he acted in 1920 as an exchange professor in the Universities of Leeds and Cambridge. The volume contains two appendices, consisting respectively of a bibliography of Sedgwick's writings and a list of his pupils.

Applied Elasticity.

Applied Elasticity. By Dr. John Prescott. Pp vii + 666. (London: Longmans, Green and Co., 1924.) 25*s* net.

A STUDY of elasticity lying midway between that provided by Love in his "Theory of Elasticity" and by Morley in his "Theory of Structures and Properties of Materials" has long been required—a book, in fact, for the mathematical engineer The present work, as its title indicates, is an attempt to fill that niche, and it contrives to do so with considerable success Incidentally it is an exposure of the narrowness of the field that has been explored mathematically with any certitude.

The first three chapters deal with the analysis of stresses, the establishment of the equations, and a few particular solutions. These are very clearly expounded. Then follows a chapter on the empirical basis of elasticity. Considering the fundamental importance of this question and how necessary it is to realise the limitations involved in the basic assumptions and therefore imposed on the results of the theory in practice, it would be reasonable to expect a considerable chapter devoted to this question. Out of nearly 670 pages, this chapter consists only of 4 pages. The next seven chapters deal with rods under tension and thrust, in torsion, rods in longitudinal and torsional oscillation, and curved rods in equilibrium. Following a chapter on spheres and cylinders come four on thin plates under various conditions of stress and one on rotating discs.

It is apparent at once that, roughly, the field amenable to mathematical analysis narrows itself down to a treatment of the simple geometrical forms—the line, the plane, the sphere, and the cylinder. Even in these

regions it is not at all apparent how far the results obtained have actual validity. When in design work, factors of safety—or ignorance—of 5, 6, and 7 are common, it cannot be expected that a piece of analysis, however beautiful or elaborate, will carry conviction unless point by point the deductions can be checked directly or indirectly by experiment. The present work, we venture to think, would have been considerably enhanced by a larger proportion of space being devoted to experimental comparison, especially for a work on applied elasticity. The limitations of the theory of Chapter vi., for example, dealing with the buckling of struts, to choose only one case, would have been apparent had some of the published results of such tests been introduced for comparison. These would have enabled one to appreciate how far the simplifications involved in assuming idealised pin-joints, homogeneity of material, and lack of eccentricity generally are reflected in the calculations After all, it is vitally important to know how far applied elasticity can be relied upon for a prediction.

The author has apparently confined his attention deliberately to certain groups of questions. There is no mention of the many applications of elasticity to aeronautics, to wing and fuselage structures, or to twisting and vibration of propeller blades But we must not be over-critical. He has undoubtedly produced an excellent and important contribution to the subject, not merely in the old matter which he has presented in new and refreshing form, but also in the many original investigations here published for the first time. We are grateful for it.

Our Bookshelf.

Handbuch der allgemeinen Chemie Herausgegeben von Prof Wilhelm Ostwald und Prof. Carl Drucker. Band 4: *Das Leitvermögen der Lösungen.* Von Prof. Paul Walden Teil 1: Allgemeines, Grundlagen der Leitfahigkeitsmessungen, Methoden, Elektrolyte und Lösungsmittel, Uberführungszahlen, Ionenchemie. Pp. ix+383 17 marks. Teil 2 und 3: Zahlenwerte des Leitvermogens in wässerigen und nichtwasserigen Losungen; Folgerungen, Gesetzmässigkeiten, Anomalien, Anwendungen. Pp. vi+346+v+397. 47 marks. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1924.)

THE fourth "volume" of Ostwald's "Handbuch der allgemeinen Chemie" consists of three parts, under the general heading of "Conductivity of Solutions." The first of these parts deals with methods of measurements, and general questions, such as the hydration of ions, and concludes with a long section on transport-numbers and ionic mobilities. The second part contains the numerical data in reference to conductivity in aqueous and non-aqueous solutions. The third part deals with regularities and anomalies, as well as the application of conductivity-measurements to the study of physico-chemical problems.

A quarter of a century ago, it was possible to deal fully with all these questions in a single small monograph. Thus Kohlrausch's "Leitvermögen der Elektrolyte," published in 1898, contained only 227 pages, including the table of contents and tables of logarithms, etc. The three sections of Prof. Walden's book cover 383, 347, and 397 pages respectively, apart from title-pages, etc., giving a total of well over 1000 pages. Like so much other German literature of this kind, the book is amazingly complete. Every paper dealing with the subject appears to have been noticed, and even the most distant applications are discussed with full references to the relevant literature. Thus an organic chemist who is interested in free radicals or in carbonium salts will find the relevant data duly catalogued. It is impossible not to admire the patience and skill of the author in compiling so complete a work, and its value to workers and teachers cannot be exaggerated. Its very completeness, however, makes it more suitable for use as a work of reference than as a text-book for students, unless as readers they possess the same amazing patience that the author has shown as a writer. One of the principal uses of the book will, however, be as a mine of information for those who are responsible for teaching the subject, and in this way its publication may prove of real value even to the elementary student, but it would be an alarming prospect if so complete a volume should be taken by his examiners as indicating what the scope of his knowledge should be.

The Military Uses of Astronomy. By Major F. C. Molesworth Pp. xii + 112 + 2 plates. (London: Longmans, Green and Co., 1924) 3*s.* 6*d.* net.

THE main impression created by reading Major Molesworth's handbook is that the task undertaken is rather a difficult one. Its object is to explain the fundamental principles of astronomy, with practical application to the simple problems which present themselves to the soldier without requiring the use of instruments. The knowledge demanded is modest enough, but to convey it in an accurate and attractive form is not easy. With the necessary deductions for full-page diagrams and so forth, this book occupies less than eighty-five pages, and, partly from its brevity, the treatment of the subject appears rather unsatisfactory. The needful familiarity with actual problems can only be gained by assiduous practice, and it seems doubtful whether Major Molesworth's little work will provide the stimulus to bring out the necessary effort.

In spite of Sir W. R. Birdwood's foreword, it seems but fair to recognise that the military uses of simple naked-eye astronomy are strictly limited. It is inconceivable that any serious operation should be left to the chances of a fine sky. There is no apparent reason why, in normal circumstances, the watch and the compass should not be used for the purpose of determining time and direction. In cases of emergency, as, for example, the escape of prisoners, readiness in making use of astronomical indications may be an invaluable resource, but only when more orthodox and trustworthy methods are not available.

This is not to be understood as discouraging in any sense the study of the elements of astronomy, which can be recommended as a thing fascinating in itself and

specially valuable alike to soldiers and to all others who are liable to find themselves removed from the normal conditions of civilised life. But it has no value which is exclusively military, and a broader foundation is desirable than will be found in this book if the more valuable sequel of practical observation is to be expected.

It should be mentioned that a special feature of the work is a set of diagrams giving for every 10° of latitude from 70° N. to 40° S. the bearing and altitude of the sun throughout the year. Something better in the way of star maps than the plates at the end of the book could easily have been provided.

A Manual for Spraying. By K. L. Cockerham. Pp. xi + 87. (New York: The Macmillan Co., 1923.) 7*s.* net.

THIS little book on spraying is intended as a reference book and guide for practical men. It is exceedingly brief, consisting of a short account of various types of spraying machines, including dusting apparatus; descriptions of and recipes for the more commonly used spray fluids; and a series of tables of insect and fungus pests, arranged under crop headings, giving the kind of injury caused by each pest and the spray recommended for its control. Unfortunately, the subject does not lend itself to quite such cut-and-dried treatment. The identification of a pest from a description of the injury, which seldom exceeds five or six words in length, is rarely likely to be successful. Moreover, the instructions for making up the spray fluids are in some cases so brief as to be incomprehensible Chemical formulæ are used to excess, frequently without any clear indication of the ordinary name of the substance; and inaccuracies and misstatements are inexcusably numerous. What is the fruit-grower to make of the following, with reference to Bordeaux mixture: "The liquid should be thoroughly tested for excess of $CuSo_4$ and $Ca(OH)_2$. If it does not respond to these tests it is unfit for the purpose for which it is intended"? Under the heading of crude petroleum we get the information: "Specific gravity of crude petroleum ranges from 1·049 (A) (ethane) to $0{\cdot}775^{18°}$ (hexadecane). Boiling-point of ethane as a solid is −86°." Sulphur dioxide has "specific gravity 1. 433680°. 2. 2639(A)." Directions for the use of nicotine sulphate are included, but not for nicotine. Many similar quotations could readily be given. If the author had left out most of the "chemistry" and devoted the space to some elaboration of the spray fluid recipes, the book might have proved useful to the growers and farmers for whom it was written. As it is, it cannot be recommended as helpful. C. T. G.

Refraction of the Eye: including Elementary Physiological Optics. By Dr. Charles Goulden. Pp. xii +276. (London: J. and A. Churchill, 1925.) 10*s.* 6*d.* net.

THE author tells us that this book is the outcome of a series of lectures which he has given at the Moorfields Eye Hospital to candidates for the new Ophthalmic Diploma of the Conjoint Board of England, and that its object is to give an exposition in as elementary a way as possible of the facts upon which the study of the refraction of the eye is based.

We may say at once that the book seems to meet these requirements in an admirable way. The headings to the seven chapters are: optics; the optical constants of the eye; the eye as an optical instrument; errors of refraction; the ophthalmoscope; retinoscopy; muscular anomalies. In this type of book the student is apt to find that the optics and mathematics are not so elementary as the author supposes; he will find, however, in Dr. Goulden's book, that the mathematics required can quite safely be called elementary, and the descriptions are all so particularly lucid that he will find little difficulty in at once grasping the facts The diagrams, of which there are one hundred and eighty, call for special praise; they are bold and clear and the lettering could not be improved upon.

It is a book that can be highly commended, not only to those whose immediate object is the negotiation of an examination test, but also to many who are well advanced along the road of ophthalmic practice and have not recently polished up such knowledge which is fundamental to the thorough understanding of much of their work. There is a very full index, the type and general get-up are excellent, and we may confidently predict a long life in future editions

Practical Forestry: from a Workman's Point of View. By A. C. Drummie. Pp. xii + 340 (London: G. Routledge and Sons, Ltd., 1924) 7*s.* 6*d* net.

THIS book is written "from a workman's point of view," and is in great measure the outpouring of one discontented with the present conditions of society in England; as such it may be left to the criticism of sociologists. As regards practical forestry, it contains nothing new or even freshly put, the matter being ill-arranged and mixed up with discussions on subjects the connexion of which with forestry is not obvious. The author, for example, "trusts readers will excuse a few remarks on the formation of coal," and proceeds to air his views: "Why is coal put between species of stone or rock? Because the Almighty put it there, and no expert or scientist breathing will ever make the writer believe otherwise." This book is unsuitable for forestry students or woodmen who require accurate description and scientific method in their manuals of instruction. It merits, however, the attention of both landowners and educationists, as its perusal shows how much remains to be done in the school and in the lecture hall to enlighten skilled workmen and artisans concerning the real aims of science.

Medical Hydrology: Outlines for Practitioners and Students. Based upon Lectures given at the University of London. By Dr. R. Fortescue Fox. Pp. viii + 136. (London: J. and A. Churchill, 1924.) 6*s.* net.

THE application of various waters in the prevention and cure of disease is one of the oldest therapeutic measures known to medical science, and in the past has been mainly empirical. In his outlines of medical hydrology, Dr. Fortescue Fox explains briefly the properties and actions of waters and discusses the rationale of treatment by their application. His conclusions are summarised in a series of aphorisms, the dogmatic wording of which is justified in the preface. The book will be useful to practitioners in exercising a choice of spas for the treatment of chronic disease.

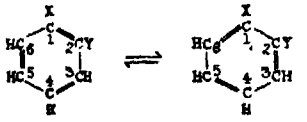
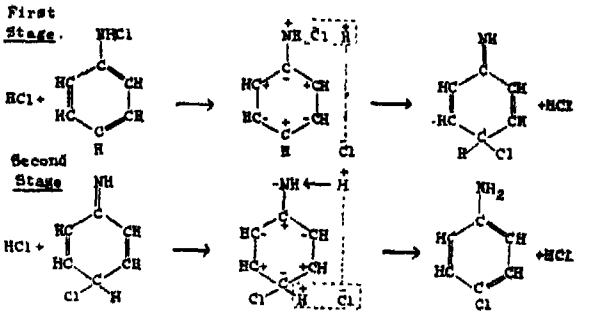


Graphitic Conduction in Conjugated Chains of Carbon Atoms: A Contribution to Armstrong's Theory of Chemical Change.

THE view put forward by Armstrong in 1885, that "chemical action is reversed electrolysis," has been brilliantly vindicated in the field of inorganic chemistry, especially by H. B Baker's experimental verification of the bold prediction that highly purified water will not determine the explosion of hydrogen and oxygen. In organic chemistry similar evidence in favour of Armstrong's theory has been afforded by the proof that a catalyst is needed even to effect the transfer of an atom of hydrogen from one part of the molecule to another in prototropic compounds such as ethyl acetoacetate or nitrocamphor

Whilst, however, it is easy to recognise that, in a chemical action between non-electrolytes, the catalyst may play the part of the *electrolyte* in a battery, and that the non-electrolytes themselves may act as *depolarisers* to the ions liberated by electrolysis, it has always been difficult to discover, in reactive systems from which metals in every form are absent, any analogue to the *metallic conductor*. Thus, we can picture the isomeric change of phenylchloroamine into parachloroaniline, $C_6H_5 \cdot NHCl \longrightarrow Cl \cdot C_6H_4 \cdot NH_2$ (in which atoms of hydrogen and chlorine change places under the influence of hydrogen chloride), as depending on a process of electrolysis whereby the catalyst is resolved into hydrogen and chlorine, the *electrolytic hydrogen* being depolarised by the chlorine which it displaces from the side-chain, and the *electrolytic chlorine* by the hydrogen atom which it displaces from the para-position in the ring This explanation, however, although complete from the chemical point of view, fails to explain the electrical action, since, in the absence of metallic conduction in the aromatic nucleus, it would leave a surplus of two electrons in the para-position and a deficit of two electrons in the side-chain, thus



$$C_6H_5 \cdot NHCl \longrightarrow \overset{-}{Cl} \cdot C_6H_4 \cdot \overset{+}{N}H_2.$$

No method of discharging these two poles has, so far as I know, been suggested hitherto; but the fact that chemical changes, and especially isomeric changes, involving distant atoms are so peculiarly characteristic of aromatic compounds, indicates that some special mechanism (producing effects equivalent to metallic conduction) must exist in these systems to render such actions possible. From a purely chemical point of view, Kekulé so long ago as 1872 attributed to the bonds of aromatic compounds a peculiar mobility, which was not found in compounds of other types, when he found it necessary to explain the identity of the 1 : 2 and 1 : 6 derivatives of benzene by a spontaneous interchange of single and double bonds, as in the following scheme:

This interchange of bonds was not regarded, however, as conferring any special electrical properties on the molecules in which it took place. A similar mechanism was used by Lapworth in 1898 to explain the facility with which hydrogen and other radicals can wander between alternate atoms in unsaturated and conjugated compounds. This was attributed to the fact that, at each stage in the migration, the valencies can be adjusted by an interchange of bonds as in the scheme suggested by Kekulé. Thus when the hydrogen and chlorine in phenylchloroamine change places, the *chlorine* was supposed to wander first from the side-chain to the ring, with a simultaneous interchange of the alternate single and double bonds in the intermediate chain of atoms. The original arrangement is, however, restored by a second interchange of single and double bonds, when the *hydrogen* wanders in the reverse direction from the ring to the side-chain

Lapworth suggested further that the radicals probably migrate *in the form of ions*, but did not put forward any mechanism for the transference of the electric charges left behind by these ions on the aromatic nucleus. If, however, we now add to the electrolytic theory of isomeric change as set out above, the view (based upon the electronic theory of valency) that *at each stage of the action the intermediate double bonds of the conjugated system are ionised*, in the manner suggested in my paper on "The Polarity of Double Bonds" (Jour Chem. Soc., 1923, 123, 822-831), it will be found that the oscillation of double and single bonds, in the manner postulated by Kekulé and by Lapworth, has supplied the one feature that was needed in order to bring this interpretation into complete harmony with Armstrong's dictum, since the oscillation of bonds makes it possible for electric charges to be handed from one end to the other of a conjugated system, without any simultaneous migration of the intermediate atoms, *i.e. by a process which is analogous to metallic and not to electrolytic conduction*. The isomeric change of phenylchloroamine can therefore be represented as follows:

The chain of molecules of the catalyst through which electrolysis proceeds is here represented by two lines, thus, $\overset{+}{H} \ldots \overset{-}{Cl}$, and, following Lapworth, the transference of the halogen is represented as preceding the transference of hydrogen, but the ionisation of the intermediate system of conjugated double bonds, first in one sense and then in the other, now prevents the accumulation of electric charges at the two poles. It is, therefore, at last possible to formulate a scheme which is just as satisfactory from the electrical as from the chemical point of view, since it reproduces in almost every detail the mechanism of an electric battery, with the possible exception of the precise way in which metallic conduction is effected.

The polarities of the carbon atoms of the ring, as shown in the first stage, are the opposite to those normally developed in derivatives of aniline; and a similar reversal is seen in the polarity of the chlorine, which is usually split off in presence of water as a *positive* ion, *e.g.* in combination with negative hydroxyl

as hypochlorous acid, or (if hydrogen chloride is present as well as water) in combination with a negative chlorine ion as gaseous chlorine. It is, therefore, suggested that the polarities shown above are induced by a cathodic reduction of the chlorine of the chloroamine, accompanied by a simultaneous anodic chlorination of the *para* CH group, and that these conditions are sufficient to produce a reversal of the normal polarities of the system.

In this connexion it is of interest to recall the fact that X-ray analysis has shown that the transparent non-conducting crystals of *diamond* are made up of quadrivalent atoms of carbon linked together tetrahedrally, just like the atoms of a saturated organic compound of the aliphatic series; but in the case of *graphite* it has confirmed the view, already established by chemical methods, that the conducting crystals of this form of carbon are built up from a network of hexagonal rings, of the same type as the conjugated systems of aromatic compounds, in which the carbon-atoms are virtually tervalent. The suggestion that conjugated chains of carbon atoms, united by alternate single and double bonds, can perform the function of a metallic conductor is therefore in harmony with physical as well as with chemical observations. Since, however, the temperature coefficient of conductivity of graphite is positive, whilst that of metals is negative, and since, moreover, we can now assert that the structure of the crystals and probably the mechanism of conduction is quite different in the two cases, it would be wiser to describe the transference of electricity through conjugated chains of carbon atoms as *graphite conduction*, rather than as metallic conduction, and this term has therefore been used at the head of this letter.

T. M. LOWRY

54 Bateman Street, Cambridge.

Influence of Radiation on Ionisation Equilibrium.

IN considering ionisation equilibrium of the type $M \rightleftarrows M^+ + e - U$, the usual method adopted is to write down the entropies of M, M^+, and e from the quantum theory, and then the law of reaction isochore is obtained from the equation $S + S' - s = -U/T$. In this way we obtain the law of ionisation equilibrium

$$\log \frac{x^2}{1-x^2} P = -\frac{U}{2{\cdot}3RT} + \frac{5}{2} \log T - 6{\cdot}5. \quad (1)$$

The system is regarded as unary (one-component), *i.e.* all the reacting electrons as well as M are derived from the ionisation of M, but when there is excess of electrons, the system is binary and the equilibrium is expressed by the form first given by H. N. Russell, namely,

$$\log \frac{x}{1-x} \cdot \frac{x'}{1+x'} P = -\frac{U}{2{\cdot}3RT} + \frac{5}{2} \log T - 6{\cdot}5. \quad (2)$$

The process is regarded as an abrupt one, M-atoms passing directly under the influence of heat to the M^+-stage, without going through the intervening metastable states. Darwin and Fowler have attempted to include these intervening states by adding to the right-hand side of equation (1) a function $B(T)$. Prof. Russell has pointed out that neither equation (1) nor (2) can be regarded as final, because it fails to take account of the possible influence of radiation and excitation of higher states. We may introduce the matter in the following way. Suppose we have a mass of sodium-vapour in the solar chromosphere. Then the ionisation of sodium atoms is determined not only by the temperature of the chromosphere (say 5000° C), but also by the intensity of photospheric radiation of wave-length λ less than the wave-length of the limit of the P series, passing through these sodium atoms. This radiation has a higher temperature than the local temperature; hence, as was first pointed out by Milne, we have no thermodynamic equilibrium in the solar chromosphere. The excited states are produced under the joint influence of temperature of the chromosphere and of the photospheric radiation passing through the chromosphere. To the same class belongs the absorption experiments of Wood and others, in which a column of sodium or other vapour is acted on by light of much greater intensity than what would be produced at the temperature of the absorbing gas. Here all the excited atoms, or ionised atoms, are produced by light only, and almost none are due to temperature.

The general problem has been thus attacked. In all photochemical reactions the equilibrium is determined by the intensity of light, and in treating these cases from the point of view of the phase rule, Smits expressed the opinion, without however giving his reason, that the ordinary Gibbs formula, $F = C + 2 - P$, must be replaced by $F = C + 3 - P$. We, however, arrive at the same result by assuming that the number of components has increased by one, the photochemically active light being regarded as a new and independent component. In other words, when a normal sodium-atom passes to the $2p$-stage by absorbing the $h\nu$-pulse of D-radiation, then either the excited atom of sodium or the pulse of light may be regarded as a new component, except when the D-light is derived from the effect of temperature prevailing in the gas. In the latter case, the system is a system of one component, as in the corresponding case of free electrons in equation (1).

We thus regard excited sodium-atoms as a compound, in a special sense, of normal sodium-atoms and D-pulse. It has been possible to deduce the equilibrium conditions in such cases by combining the methods given by S. N. Bose (*Zs. f. Physik*, vol. 27, p. 384) and P. Ehrenfest. We give only the final results. If ρ_ν be the density of radiation which is absorbed, and if n_1 and n_2 be the concentration of atoms in the normal and excited states,

$$\frac{n_2}{n_1} = \frac{g_2}{g_1} \frac{\rho_\nu}{8\pi(h\nu^3/c^3) + \rho_\nu}. \quad (3)$$

When the light is derived from the temperature of the system we can put

$$\rho_\nu = 8\pi \frac{h\nu^3}{c^3} \frac{1}{e^{h\nu/kT} - 1},$$

and we have

$$\frac{n_2}{n_1} = \frac{g_2}{g_1} e^{-h\nu/kT}, \quad (3a)$$

as is usually obtained from direct application of Maxwell's law, and g_1, g_2 are the weights of the two states. If ρ_ν is very large

$$\frac{n_2}{n_1} = \frac{g_2}{g_1}, \quad (3b)$$

as we can expect from the definition of g_1 and g_2.

In the case of ionisation, let ν be the frequency of ionising radiation (supposed monochromatic). Then the law of ionisation is given by

$$\log \frac{x^2}{1-x^2} P = -\frac{(U - Nh\nu)}{2{\cdot}3RT} + \log\left(\frac{\rho_\nu}{8\pi(h\nu^3/c^3) + \rho_\nu}\right) + \frac{5}{2} \log T - 6{\cdot}5, \quad (4)$$

where $N = R/k$.

If

$$\rho_\nu = \frac{8\pi h\nu^3}{c^3} \frac{1}{e^{h\nu/kT} - 1},$$

i.e. radiation is due to the temperature of the system, (4) reduces to

$$\log \frac{x^2}{1-x^2} P = -\frac{U}{2{\cdot}3RT} + \frac{5}{2}\log T - 6{\cdot}5, \qquad (4a)$$

as is obtained directly from thermodynamical theories.

Equation (4) expresses equilibrium in a two-component system, equation (4*a*) in a one-component system.

Of course the ionising power is not limited to one single radiation, nor are all pulses of frequency $\nu > \nu_0$ (ν_0 = convergence frequency of the principal series) equally effective in causing ionisation. But these facts can be taken into consideration in the method used above.

The Future of the Meteorological Office.

DR G C SIMPSON writes (NATURE, February 14) that he is sure I should not wish my remarks on the future of the Meteorological Office to be taken as more than my own personal opinion; but on the contrary I believe that my views are shared by a large number of meteorologists In 1920 the Royal Meteorological Society adopted a resolution regretting that the Meteorological Office had been placed under a Government department, created for another purpose, and urging that the Meteorological Committee should again have control, it was also pointed out that, when in the past changes had been made in the status of the Office, inquiries had been held On this occasion, since no report has been issued, we must conclude that the transfer of the Meteorological Office to the Air Ministry took place with no public inquiry, and to an outsider it appeared to have been made in a hurried and even arbitrary manner

The fear that the Meteorological Office may become a mere forecasting department of the Air Ministry, which is what I meant when I said that the future is uncertain, is not dispelled by Dr Simpson's reference to the "complicated meteorological service for aviation with its thirteen stations on aerodromes." The cares of hourly reports for aviators are not conducive to the development of scientific ideas, and a Government department which has such claims on the Meteorological Office may, under pressure for economy, neglect those aspects of meteorology not directly connected with immediate requirements. The pressure for economy may very likely prove stronger than an advisory committee. It is with misgiving that one notices the giving up of the radio research station at Smallshot Hill (now fortunately taken over by the Radio Research Board), and the transfer of upper air research from Benson, originally chosen for its suitability for *ballons-sondes*, to Kew, where it is in charge of an assistant-superintendent in place of a director of experiments. These researches, of great promise for the study of the atmosphere, were at the time of the change of no immediate utility to the Flying Service. When one considers the real additions to our knowledge of the atmosphere that have come from the freedom and seclusion of Pyrton Hill and Benson, it is almost painful to contemplate the rigorous conditions of a ministry as a nursery of research. Such changes inspire the fear that other researches not directly connected with flying may be dealt with in like manner.

If the Meteorological Office is to be only a forecasting office the chief work of which is for the Flying Service, I agree that it could not be in a better position than at present, but if it is still to be an instrument for the advance of the more purely scientific aspects of meteorology I am forced, despite the larger financial grant, to agree with the resolution of the Royal Meteorological Society. I regret that I am constrained to disagree with Dr. Simpson in this matter, the more so as I am indebted to him for continued help in many meteorological matters ever since he became Director. I sincerely hope that he will be right and that I shall be wrong; but that the future only can decide. In the matter of the present staff of the Meteorological Office I am in absolute agreement with Dr Simpson, and I used the following words in my address. "The staff of the Office is composed of men of the highest scientific calibre; probably never before in its history has it contained such a galaxy of talent"

The Michelson-Morley Experiment.

IN their scheme of their experiment, Michelson and Morley selected a single incident ray, showed how this would divide into a transmitted and a reflected moiety, traced out the path-lengths and found the difference δ Then, comparing the results in two orientations, they computed the difference $\delta_2 - \delta_1$, which they estimated at $l \times 2\beta^2 = (0{\cdot}00000002)l$ when $\beta = v/c = 10^{-4}$ and the semi-translucent mirror is set at $\theta = 45°$ They applied this computed difference of path-differences to predict a shift of bands in an interference-field; but they did not go into the question how the interference-field (which is undoubtedly observed) is produced.

The only way in which the scheme would work is to assume that the two virtual images of a point on the incident wave-front, formed by the two moieties from the single incident ray, themselves act as two virtual point-sources, capable of producing an interference-field. Also, there must be some definite observation point within the interference-field.

It does not seem to me to be reasonable to assume that the virtual images would act as luminous point-sources, because there would only be one ray to each virtual image, derived from the single incident ray.

I have worked out the precise positions of the final virtual images and the precise single reflected rays passing through these; all as definite functions of c, v and the constants of the apparatus including θ; and I have found a reasonable observation-point, to be reached by the observing eye in a time t.

Then, waiving objections to it for the moment, I have followed up the above implied assumption and calculated out the values of $(\delta_2 - \delta_1)$ for various values of v and various settings θ of the semi-translucent mirror. The results are remarkable and unexpected.

Let the apparatus be ideally constructed; true right angles, equal arms, etc. Let the semi-translucent mirror be set at an exact 45°; and let v be the full $c \times 10^{-4}$. Then (*a*) in both orientations the virtual images, assumed radiant, would be too close together (less than $\frac{1}{4}\lambda$ for yellow light) to produce any interference-field at all; and (*b*) $\delta_2 - \delta_1 = (0{\cdot}0000,0000,0003,0002)l$.

Therefore, on the single-ray scheme, when $\theta = 45°$ and $v = c \times 10^{-4}$, there ought to be no observable effect, not even an interference-field. With θ still at 45°, but $v > c \times 10^{-4}$, as v increases the virtual images are farther apart, and if they acted as virtual point-

sources, an interference-field would begin to be possible until, at a certain large value of v, the breadth of bands would correspond to that actually observed. The immediate neighbourhood of $\theta = 45°$ is a region of extraordinary sensitiveness, in which $(\delta_2 - \delta_1)$ passes twice through a zero value. Very minute changes in θ make very great changes in the value of $(\delta_2 - \delta_1)$.

The numerical data do not lend themselves to any general statement as to the value of v; but they point towards an actual value of v much greater than $c \times 10^{-4}$, however this may be accounted for. So far for the single-ray scheme, with the assumption required by it.

I prefer to deal not with a single incident ray but with an incident plane wave-front, and to study the kind of interference-field necessarily formed where the two reflected moiety-wave-fronts cross one another. Each virtual "image" of the previous working now appears as a point on a virtual plane wave-front, which is at right angles to the corresponding "single reflected ray" of the previous working. The working out is straightforward and unforced; and it again leads to remarkable and unexpected results.

Assuming θ to be an exact 45°, and $l = 1100$ cm. in an apparatus of ideal construction as above; then with yellow light ($\lambda = 0{\cdot}00005892$ cm.) we have in the first orientation a band-breadth of 11784 cm. if $v = c \times 10^{-4}$, 117·84 cm. if $v = c \times 10^{-3}$; 1·1784 cm if $v = c \times 10^{-2}$; and 0·011784 cm if $v = c \times 10^{-1}$

Assuming v to be $c \times 10^{-4}$, we similarly have band-breadths 0·0059 cm. if $\theta = 45° + 1024''$, 0·59 cm. if $\theta = 45° + 10''{\cdot}3$, 3928 cm. if $\theta = 45° + 0''{\cdot}001$, 11784 cm if $\theta = 45°$, ∞ if $\theta = 45° - 0''{\cdot}0005$, 11784 cm. if $\theta = 45° - 0''{\cdot}001$, 59·22 cm. if $\theta = 45° - 0''{\cdot}103$, 0·59 cm. if $\theta = 45° - 10''{\cdot}3$; 0·0059 cm. if $\theta = 45° - 1036''{\cdot}43$.

Working out and tabulating combinations of various θ's and v's and orientations we might hope, if we had an extraordinarily accurate knowledge of the lengths and angles involved, to be able to reach a conclusion as to the operative value of v from the band-breadths alone. The comparative shift of bands as between two orientations is not helpful in this respect; it depends upon a remainder in decimal places only, where we do not know either l or λ to a sufficient number of working figures. ALFRED DANIELL.

P.S.—By the courtesy of the Editor I have seen Sir Oliver Lodge's comment on the above letter. May I explain further that no bands would or ought to appear unless the instrument be in sufficiently rapid motion *when the semi-translucent mirror is set at an exact* $\theta = 45°$; if at any other angle, there will always be a certain amount of separation of the virtual images which may not be sufficient to produce an interference-field until aided by a sufficient velocity of movement (smaller than in the former case) producing a farther separation of the virtual images. The breadth of bands is a function of θ and v.

THE Michelson-Morley experiment looked for a shift of well-known interference-bands, about the formation of which there was no doubt or controversy. Ordinary wave theory explains the appearance of these bands with ease. Dr. Daniell, however, claims that no bands would or ought to appear unless the instrument was in motion, and that the width of the bands is itself an indication of the rapidity of motion, which is thereby proven to have a high value. This view is so hopelessly unorthodox that it is difficult to regard it with equanimity. Probably he is attending to one single precise ray—whatever that may be—and not to a small portion of a wave-front, with its inevitable slight obliquities. OLIVER LODGE.

The Theory of Hearing.

IN his letter in NATURE of February 14, p. 228, Prof. Scripture directs attention to the valuable work on the theory of hearing done at the New York research laboratories of the American Telephone and Telegraph Company. He refers to the papers of Fletcher, and of Wegel and Lane The results obtained by these experimenters, in his opinion, completely confute the resonance theory, though he considers that "The simple facts of the accelerated toothed wheel and of portamento speech . . ought to have been enough to convince any one."

All minds do not function alike, and those propositions which appear self-evident to one are by no means so to another. As an illustration of this truism one finds that Prof. Scripture, though he avails himself readily of the experimental results in question, rejects at once as unworthy of serious consideration the interpretation of those results given by the experimenters themselves To him it appears self-evident that the results are wholly inconsistent with the resonance theory, though the experimenters state their conclusions in terms of that modification of the resonance theory to which they give the name, the "dynamic theory."

The cochlea as conceived by Wegel and Lane is a highly damped resonating organ giving more or less localised responses to simple tones conveyed to it. The pitch of the tones heard is determined by the maximum points of the disturbances in the basilar membrane By the term "non-linear" response they imply (as seems to the writer) that the relation at various pitch levels between the intensity of the impulse and the loudness of the tone heard cannot be expressed graphically by a straight line From this they deduce the generation of combination tones and subjective harmonics in the cochlea Their theoretical deductions from the results of their experiments are perhaps vitiated by reason of their having left out of consideration the progressive graduation in tension of the basilar fibres by the spiral ligament. In any case there is nothing in them inconsistent with the resonance theory

Fletcher's results are indeed startling at first sight. The elimination of the fundamental and the first four upper partials from a clarinet tone produced no alteration of the pitch of the tone, the fundamental still appearing as the characteristic pitch He explains this as being due to the difference tone generated by the remaining partials To Prof. Scripture this explanation appears so surprising that he can only express his feelings by a note of exclamation To the writer the suggestion appears rational, and indeed inevitable. Are we to understand that Prof. Scripture does not believe in the existence of the subjective difference tone? Prof D. C Miller has analysed the clarinet tone He states that it may have twenty or more partials, with the seventh to the tenth predominating This latter group of partials are even stronger than the fundamental, and it is they which are chiefly concerned with giving the characteristic quality to the tone of the instrument. The difference tone of each successive pair of partials would, of course, have the same pitch as the fundamental. Even after the elimination of the five lowest partials, there would still remain fourteen pairs of generators to supply this difference tone. Possibly not all the partials would have sufficient intensity to act as generators, but the four predominating partials probably would. All these experimenters ascribe the generation of the difference tone to the cochlea, and not to the middle ear, as Helmholtz suggested. The writer has advocated the same view elsewhere, though not on the same grounds.

Prof. Scripture states that his deformation theory is capable of explaining these, and indeed all other phenomena of sound perception. Against this claim the writer feels impelled to enter a protest. So far as he is aware, Prof. Scripture has never formulated a theory of hearing. He has stated six "theses" (NATURE, April 26, 1924, p. 605), none of them new, and all of them highly disputable, on which he proposes to construct a theory. Now to the writer a "thesis" means a proposition stated for the purpose of proof or attempted proof. No such proof has been brought forward. To traverse these theses seriatim would be to review the controversies of the last sixty years. The writer is unable to recognise any material points of difference between the theory foreshadowed in the theses and the "pressure pattern" theories of Waller and Ewald, which he has discussed to the best of his ability elsewhere. He has already stated his objections in NATURE (May 31, 1924, p. 781) to some of the chief points of the theses, without eliciting any reply.

On the question of the nature of vowel sounds Prof. Scripture speaks as an authority, but one may be permitted to point out that he is not in agreement with other authorities. Prof. Miller states "The results of the work here described [on the analysis of vowel sounds] are in entire agreement with Helmholtz's theory, and are therefore out of harmony with Scripture's arguments."[1] Later, he speaks of the fundamental tone of the vowel being generated in the larynx.[2] When authorities differ, no single one of them is in a position to impose his own views as absolute.

In any case the simple piano experiments described by Helmholtz and Ellis, and referred to in my former letters (NATURE, May 31, p. 781, and July 19, 1924, p. 87), afford direct evidence that vowel sounds are capable of being analysed by resonators, and consequently weaken any indirect argument against the resonance theory which may be deduced from the supposed nature of vowel sounds.

G. WILKINSON

Sheffield.

Ecology of Moorland Plants.

IN an article upon this subject in NATURE of November 8, Prof. Priestley discusses the apparently xerophilous nature of the ericoid shoot, and concludes that a plant such as Calluna is better classed as a "xeromorphic mesophyte," which is "able to lose water like a mesophyte because in its natural habitat plenty of water is practically always available." This conclusion is preceded by a brief reference to the recent work of Stocker and Montfort showing that the water of moorland soils is not necessarily toxic to moorland plants, and does not, as Schimper suggested, diminish their effective water absorption. Prof. Priestley accepts their inference from these experimental results and states that the "physiological dryness" of a peaty soil is a "myth," and that therefore "there is not much left of the case for the xerophytic character of Calluna and the ericoid shoot."

I should like to point out that such experiments as those quoted are far from proving the non-xerophilous nature of the ericoid shoot, though they doubtless throw light on the very intriguing question of the water relations of ericoid shoots and leaves. It is true that structural features such as rolled leaves, thick cuticle, and protected stomata do not necessarily indicate xerophily; but the mere capacity for active transpiration during plentiful water absorption certainly does not prove the contrary.

The character common to all xerophytes properly so called is that of resistance to *drought* by any means, water storage, reduction of surface, etc. This has become increasingly clear from numerous observations and experiments of late years (cf. Holtermann, 1907, Fitting, 1911; Macdougall, 1912; Kamerling, 1914; Delf, 1915; the Maximows, 1924). The drought may arise either from atmospheric or from edaphic conditions, and may vary from a brief daily stress, as in the mangroves described by Holtermann (1907), to a prolonged water shortage, as in some typical Cactaceæ, but in either case the xerophyte can endure to lose water (often as much as about half its water content) without harm, whereas in mesophytic plants under the same conditions the leaves are wilted beyond recovery.

How far Calluna and other British Ericaceæ have this drought-resisting capacity has never, so far as I am aware, been tested, but the careful investigations of Thoday (1923) show beyond doubt that Passerina, a South African plant of similar "ericoid" habit and structure, possesses it in a marked degree. The water content of leafy shoots of Passerina gathered in the dry season varied from 25 per cent. to 45 per cent. (averaging about 30 per cent.) of the fresh weight; the water content of specimens taken in the rainy season being usually about 60 per cent. The shoots can thus lose quite half their normal water content without injury.

The case for the xerophily of the ericoid leaves of the British Ericaceæ, though unproven, is thus still highly probable, whatever be the absorptive capacity of the root system when *sufficient* water is available. It is, however, scarcely necessary to point out that, when water is present in the soil, it is not *necessarily* "available" to the plant in the physiological sense of the word, apart from any question of toxicity. "Availability" is estimated as that fraction of the water content of the soil at saturation which can be withdrawn by a well-established rooted plant before wilting can be detected. The wilting point depends upon the constitution of the plant as well as upon other factors. It was shown by Crump in 1911 that when Calluna grows on acidic peat only four-fifths of the soil water is available. That is, if we call the water content of the saturated soil, reckoned per unit of dry weight, 100, signs of wilting will occur in Calluna whenever the remaining soil water has become reduced to 20. In *Erica tetralix* growing in the same soil, the signs of wilting occur when as much as 30 per cent. remains. Such plants may thus have apparently "plenty" of water but actually a water deficit (especially if transpiration is active at the time), which is exactly what would be expected from their structure. It is not known how this condition of incipient wilting in Calluna reacts on the transpiration rate, but measurements of the water content of the plant as it occurs in Nature would probably reveal a much wider variation than is tolerated by plants of a typical mesophytic habit.

Further experimental work is obviously needed before any more definite conclusions are drawn as to the xerophily of the Ericaceæ. Whether their peculiar structure arises as "a natural developmental consequence of the characteristic metabolism of a root system growing in a soil that lacks sufficient aeration," as Prof. Priestley suggests, is an entirely different question which is independent of the possible significance of the final differentiation attained.

E. M. DELF.

(University of London).

[1] "The Science of Musical Sounds," D. C. Miller, p. 217.
[2] *Ibid.* p. 242.

APART from the fact that the conclusion that Calluna is a "xeromorphic mesophyte" should be attributed to Stocker, there is nothing in Dr. Delf's remarks with which I find myself in disagreement, except with regard to their relevance to the point at issue.

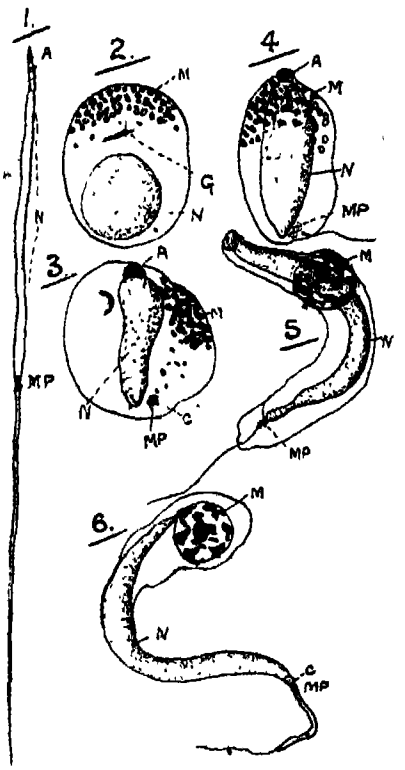
Certain features of the structure of moorland plants, inrolled leaves, sunk stomata, thick cuticle, etc., have been explained teleologically as designed to reduce transpiration. Stocker and Montfort show experimentally that the plants transpire very freely in spite of these features. Dr. Delf does not help the teleological argument by pointing out that, even though they lose water freely, the plants may still thrive because of other xerophytic characteristics Nor are Crump's results relevant to the problem of moorland plants growing in regions of excessive rainfall. The contemplation of these same "xerophytic" structural features in such swampy moorland regions had led to the suggestion that the water might not be "physiologically" available, but Montfort's experimental results show that plants absorb it freely.

It interested me very much to learn, from the presidential address of Prof. F. E. Weiss to the Ecological Society on January 10 last, that these same structural features provide a similar puzzle to the palæobotanist. On one hand, it is argued from such leaf characters that the coal measure forests grew under xerophytic conditions; on the other, from root systems and other features, it is argued that they grew in vast swamps. J. H. PRIESTLEY.

The Need for a Universal Language.

NOBODY, not even Prof Kent or Mr Heron-Allen, really wants Latin as a universal language. Latin is dead; its natural development has ceased and could not possibly meet the growing needs of international thought. Every one recognises that the classical tongue, if it is to satisfy modern needs, must have its grammar simplified and its vocabulary, especially of abstract terms, enlarged. But the features which are to be changed are those which give Latin its peculiar savour and the educational value that some would claim for it. "Modernised Latin" is not Latin at all; it is a hybrid jargon as artificial as Volapuk or Esperanto, as devoid of literary tradition, as incapable of artistic expression, as subject to national and individual vagaries. Of this last defect, of which he accuses Esperanto, Mr. Allen gives a crushing example. Few but English speakers would understand *statio* for railway-station; few but blundering schoolboys would use *quae* as a substantive for *quis*.

The Latinists are crying for the moon. They want as a medium for international communication a "natural" language with at least the possibility of literature. The thing is impossible. To fulfil its object the medium must mean the same thing to all men, however diverse their mentality or experience. The allusiveness that makes literature possible is the fruit of a common life and history; it is the fruit of that nationalist sentiment which it is one of the main purposes of the language to remove. Universal intelligibility and artistic expressiveness can never be combined in a single medium; for art is the trick of meaning rather more than you say. I hope nobody will reply that, if a universal language must always be divorced from literature, we are better without it. That was the fallacy of Ruskin and the cause of most of the sordidness of the Victorian age. An art which seeks to limit utility is doomed; and if literature is set in opposition to scientifically impersonal expression, literature will wither.



Of course, the view is tenable that modernised "Latin," confessedly artificial and developed from the language of the Romans by some conventional scheme, would be better than its rivals even according to their standards. But it is much more important to have some international language than to have the best conceivable. Esperanto is within the bounds of practical possibility; it has made definite progress; it is supported by an enthusiastic organisation; it is actually being broadcast. For the great mass of the unlearned, anything called Latin is eternally damned by its associations. To some it suggests examinations and school punishments, to others pedantry and obscurantism. It is not a practical possibility, and those who press its claims are merely hampering the cause they profess to serve

NORMAN R. CAMPBELL.

Spermatogenesis of Peripatus.

THIRTEEN years ago Montgomery, an American cytologist, published a paper in the *Biological Bulletin*, claiming that in Peripatus there was complete rejection of the mitochondria during spermateleosis. This work has been widely quoted as strong evidence against the Meves' mitochondrial idioplasm theory; but Montgomery's investigation has never since been confirmed or denied

Owing to the good offices of Prof. Gilchrist, of Cape Town, South Africa, and of Canon Forrester, Chaplain of Trinity College, Dublin, six small specimens of the Cape Peripatus arrived alive in Dublin, and I was able to procure some fairly good sections showing spermatogenesis.

At first I believed that Montgomery was correct, but latterly I have modified my views. In Fig 1, it will be seen that the middle-piece (MP) is very small — probably proportionately smaller than that of any other animal; consequently the problem of its manner of formation is not easy to solve. Figs. 2, 3, 4, and 5 show the mitochondria at M, finally forming a ball, as claimed by Montgomery. This ball is certainly extruded (Fig. 6) as explained by Montgomery, but if one examines a large number of well fixed cells at the stages depicted in Figs. 3, 4, and 5, one will nearly always find a number of fine granules (MP) which eventually form the middle-piece of the tail. I think that these granules are of the nature of mitochondria, because their reactions are similar, and I have got the impression that the middle-piece of the Peripatus sperm is formed from a few of the finer

mitochondria, whereas the main bulk of the coarse granules are rejected. In dealing with such a small cell, and when such small quantities of material are involved, it is not possible to be more explicit. It can be said with certainty that the middle-piece is formed from definite granules which do not appear to be secreted *per se* in the ground cytoplasm.

Intermetallic Reactions in a Lead-base Bearing Metal.

AN investigation into the influence of pouring temperatures and mould temperatures on the microstructure of a lead-base bearing metal of the following percentage composition (lead, 82·5, antimony, 11·0, tin, 5·5; copper, 1·0) has shown that it is possible for the antimony to unite either with the tin, to form cubes of the compound SnSb, or with the copper, to form needles of the compound Cu_2Sb (Regulus of Venus). Three different pouring temperatures have been employed in this investigation—500° C., 400° C. and 300° C. It has been found that chill castings poured at the higher temperatures—500° C. and 400° C.—contain but slight traces of the tin-antimony compound, whereas chill castings poured at 300° C. contain but few of the purple needles of the copper-antimony compound. If a chill casting containing the tin-antimony compound (that is, one poured originally at 300° C.) be melted and poured at 500° C., the tin-antimony cubes are almost completely replaced by copper-antimony needles. If, however, a chill casting containing the copper-antimony compound (that is, one poured originally at 500° C.) be melted and poured immediately on arrival at 300° C., the copper-antimony needles persist. That the copper-antimony needles may, however, be replaced by tin-antimony cubes is shown by the fact that when a sample of the alloy is heated to 500° C. and allowed to cool slowly to 300° C. before pouring, cubes of tin-antimony compound are found in the chill casting produced.

It is believed that the above observations are new. I should be glad, however, to hear if reactions of a similar nature have been observed in alloys of this or other systems.

The Auroral Green Line.

(By Cable.)

DR. SHRUM and I have observed in the spectrum of a mixture of air and helium, with the latter in excess, a line at 5577·35±0·15. Mixtures of oxygen and helium give the line enhanced approximately to one-half the intensity of each of the yellow lines of helium.

A long discharge tube was used, surrounded over part of its length with liquid air, and the best results were obtained with a pressure of about five millimetres of mercury. The line was not observable in the spectrum of purified oxygen, hydrogen, nitrogen, or helium. No mixtures of any two of these gases other than oxygen and helium gave this spectral line.

The line is narrow, very sharp, and well defined, and these characteristics, together with its wave-length and the conditions under which it is observable, point to its identity with the auroral green line.

Demonstration of the Heating Effect of a Magnetic Field.

To demonstrate the heating effect of a magnetic field, Tyndall revolved between the poles of an electro-magnet a copper-pipe filled with an easy melting fuse: the heat disengaged in it by eddy-currents melts the fuse and the liquid metal is sprayed out in visible globules. To render the heating effect of eddy-currents even more conspicuous, it occurred to me to make the revolving body to glow, and I adopted, after some trials, the following arrangement.

I used as a *rotor* (*Fig. 1*) a copper-ball fixed to a

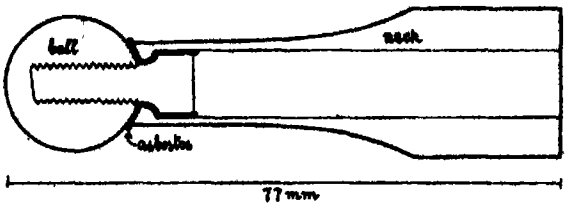

FIG. 1.

copper-neck, and insulated from it by asbestos. The rotor was fixed by the neck to the shaft of an electro-motor—the neck being sufficiently long to allow the ball to be placed in the magnetic field between the poles of the electro-magnet.

Revolving a ball 22 mm. in diameter in a field of $5·7 \times 10^3$ C.G.S. at a rate of 5½ thousand revolutions per minute, the ball begins to glow in a dark room after 1½ minutes, and in a fairly dark room after 1½ minutes.

Omitting the asbestos insulation between the ball and the neck delays the beginning of the glow by about a minute.

The Propagation of Radio Waves over the Earth.

THE modified form of the ionic deflexion theory of wave propagation, discussed by Messrs. Nichols and Schelling (NATURE, March 7, vol. 115, p. 334), appears to have been suggested in England and the United States almost simultaneously. That the effect of the earth's magnetic field had to be taken into account in calculating the phase-velocity was pointed out in a paper on "Geophysical Influences on the Transmission of Wireless Waves" read at a joint discussion of the Physical Society of London and the Royal Meteorological Society in November 1924 and already published. The formula for the phase-velocity for transmission along the earth's magnetic field and the calculation of the critical frequencies were there given, and some consequences of these effects have been discussed in a paper communicated to the Cambridge Philosophical Society. Since the earth's magnetic field is strong enough to affect the phase-velocity to a sufficient extent, all the rotatory and double refraction effects familiar in physical optics are appreciable. But probably the most interesting possibility is that the reciprocity relation between two wireless stations may not hold, for the extra forces on the moving electrons due to the earth's magnetic field are, to a certain extent, independent of the direction of propagation of the waves and thus produce relatively different effects for the two directions of transmission.

Biographical Byways.[1]

By Sir ARTHUR SCHUSTER, F.R.S.

II. HENRY WILDE (1833–1919).

HENRY WILDE would have taken a very prominent place among the scientific men of his time had his exceptional abilities not been handicapped by an obstinate and querulous disposition. He had imagination, ingenuity, and considerable experimental skill, but on the other hand he was possessed by vanity, pugnacity, and contempt for anybody else's opinion. In his scientific work he had a good sense of discrimination between the essential and the accidental, but in his personal relations with others, trivial grievances were magnified into serious injuries. Once he complained to the Vice-Chancellor of the University of Manchester that one of his clerks had insulted him. After an expression of regret and on a request for details, it appeared that the clerk, by an oversight, had omitted to put "F.R.S." after his name on a letter.

The threat of legal proceedings was Wilde's favourite method of controversy, and he was reported to have offered his solicitors twice the usual fees on condition that they should never dissuade him from taking legal action I once asked him why he was so fond of going to law. He replied that it was out of gratitude; and explained that early in his career, while he was the defendant in a law suit, the judge put a question to him which he could not answer, but when he was thinking about the matter on his way home, he was led to the train of thought which resulted in the construction of the first dynamo-electric machine. One would like to know the name of the judge and the exact nature of the question. The law suit referred to was probably that brought by the Universal Private Telegraph Company against Wilde for infringement of patent; the case was decided in his favour.

During the greater part of his scientific life, Wilde was afflicted by a sense of injury, due to what he looked upon as an insufficient recognition of his claim to have invented the dynamo-electric machine. This culminated ultimately in an unfortunate law suit which Wilde brought against Silvanus P. Thompson, who in his well-known treatise had stated that Werner Siemens, in a communication read before the Berlin Academy of Sciences on July 17, 1868, first used the expression to designate all appliances which now pass under the collective name of "Dynamos." Wilde, on the other hand, claimed that the term was first applied to his own machine by Brooke. Thompson was certainly inaccurate in his statement. In the only sentence in which the expression "dynamo-electric" was used by Siemens, it denotes what we now should call "motors." It is a pleasure to add that while Silvanus Thompson won his case both in the first instance and on appeal, he afterwards revised the historical account given in his treatise, recognising Wilde's work in a manner that is not only adequate but even generous.

Disregarding questions of nomenclature, there is no doubt that Wilde's paper, communicated to the Royal Society by Faraday in 1866, was the first important step in the production of electric currents on a scale which opened out the possibility of great industrial applications. Stokes more than once referred, in conversation, to the great impression created at the meeting of the Royal Society when an iron wire, fifteen inches long and one-quarter of an inch in diameter, was raised to white heat and melted.

Mr Haldane Gee, of the University of Manchester, in his obituary notice of Henry Wilde (Memoirs of the Manchester Lit. and Phil. Soc. vol 43, No. 5), which contains much interesting information, tells us that Wilde was the son of a working man and was apprenticed to an engineering firm at the age of sixteen. Whatever the social status of his parents may have been, his early surroundings must have been refined and cultured. Though self-taught, his language and style of writing were those of a highly educated man The extent of his knowledge of the history of science and philosophy, as well as his acquaintance with general literature, were remarkable.

Wilde's contributions to technical science were both numerous and important, but in his later years practical applications interested him mainly in a financial sense. It will be remembered that when the general public was brought to realise, almost suddenly, that the electric lighting of houses would come into general use, a panic set in among the shareholders of gas companies. Wilde, with clear foresight, chose the moment when the shares were at their lowest, sold his electric works and invested the proceeds in the General Gas and Coke Company. This, together with the royalties he received, secured him a substantial income, and he could thenceforward devote himself to unremunerative work.

Apart from his papers on terrestrial magnetism, to which he devoted much time, and excepting the subject of aviation, Wilde concentrated his attention in later years mainly on questions of a fundamental character. In these, his self-trained mind felt itself free to disregard all authority and to be guided only by his own instincts. Facts were, to him, simply illustrations to be accepted or rejected according as they did or did not fit in with his own views. His firm belief in the evidence of an intelligent design in Nature, which was the basis of his religious and scientific faith, convinced him of the necessary simplicity not only of fundamental laws but also of fundamental facts. Hence his absolute rejection of anything but integer numbers to express physical or chemical relationships. If chemists gave fractional figures for their atomic weights, their measurements, in Wilde's judgment, were necessarily wrong, and if simplicity rules the world, atomic weights were likely to follow the same order as planetary distances, with regard to which he gave unqualified assent to Bode's Law.

For the subject of the annual "Wilde Lecture" of the Manchester Literary and Philosophical Society, which he had endowed and himself delivered in 1902, Wilde selected the old-standing controversy between the followers of Newton and Leibnitz on the measurement of force. To him force meant energy, and he naturally put himself on the side of Leibnitz. The lecture, to which he gave the title, "On the Evolution

[1] Continued from p. 343.

of the Mental Faculties in Relation to some Fundamental Principles of Motion," was a great effort of special pleading, and contains references to passages in the writings of Bacon, Locke, Halley, Copernicus, De Morgan, Descartes, Newton, MacLaurin, Schopenhauer, and more modern writers. As an example of Wilde's style, the second paragraph of the lecture may be quoted:

> "It will be universally allowed that if one of the Simiinæ could be taught to enunciate a false proposition, *e.g.*, that space is four dimensional, or that the twentieth century commenced on January 1st, 1900, such a creature would be much more interesting to naturalists, and be more highly valued by collectors, than any of its inarticulate companions of the forest."

Wilde had a grim sense of humour. When some act of the University of Manchester displeased him, one could feel pretty sure that he would give effect to his displeasure by a benefaction to some other scientific institution, generally at Oxford or Paris. He once asked the treasurer and an important member of the council of Owens College to call on him on an important matter. Hopes of a substantial endowment ran high, but they had to hide their disappointment when they found that their presence was only wanted to witness a signature or to assist at some similar trivial function. Wilde's residence stood near the top of a steep lane on Alderley Edge. When bicycling came into fashion several accidents occurred at that point, and Wilde fixed on the usual danger-post a board which carried, beneath the drawing of a skull and cross bones, the legend: "A stretcher may be obtained at the Hurst Cottage below when required." A picture of the post, in its surroundings and with two cyclists inspecting it, appeared in the *Daily Graphic* on September 11, 1900.

Wilde received blows as cheerfully as he dealt them out. It was once my disagreeable task to propose a vote of censure on him while he was sitting in the presidential chair at the Literary and Philosophical Society of Manchester. He had written a letter making unjustifiable accusations against the treasurer of the Society, and some action became necessary. I first gave him an opportunity of withdrawing the letter, but he refused, and when I had made my speech and it came to the vote, Wilde simply said, "I withdraw the letter," and went on with the business of the meeting. "I have had many pinpricks from you, but you have also done me some kind actions," was all the reference he made to the incident after the meeting. Our friendship was never affected by such incidents. He might, at the end of a long discussion during one of his frequent visits to my laboratory, tell me that I was not fit to be a university professor, and a day or two later make amends by sending me a basket of beautiful hot-house grapes.

Wilde's fondness for litigation has already been mentioned. One might almost say that he looked upon it as a form of recreation. I have before me copies of lawyer's letters filling nearly twenty pages, all containing threats of legal action against the Manchester Literary and Philosophical Society, which he truly loved and of which he was a munificent benefactor. It is not necessary to enter into details with regard to them, but his dispute with the Royal Society of Arts deserves to be placed on record, and as an introduction to it I must refer to a previous incident.

Wilde had given a sum of money to the Manchester Society to enable it to award from time to time a gold medal for meritorious work. The Society considered it appropriate to offer the first medal to the donor. Knowing his sensitiveness with regard to the discovery of the dynamo machines, they laid great stress on it in formulating the reasons for the award. Wilde was up in arms: "Your Society," he told the Council, "is a body for the prosecution of pure science. You have nothing to do with technical applications." He refused to accept the medal unless the Council modified their reasons for the award, emphasising his discoveries in pure science. The Council did not see its way to accept Wilde's own formula and the matter proceeded no further. In the following year (1900), the Council of the Royal Society of Arts decided to confer the Albert Medal on Wilde "for the discovery and practical demonstration of the indefinite increase of the magnetic and electric forces from quantities indefinitely small." Wilde again raised objections. The Royal Society of Arts, unlike the Manchester Society, was concerned with industrial applications, while the wording of their award laid stress on a principle rather than on an application. This aroused his suspicion that his claim to the invention of the dynamo and its application to industrial processes was not sufficiently recognised by the Society. In his reply to the letter conveying the award of the medal, Wilde wrote:

> "Considering that the principal object of the Society is to give encouragement to Arts, Manufactures, and Commerce, which object is prominently set forth in most of the awards of the Albert Medal hitherto made, the absence of all reference to the industrial applications of my discoveries and inventions in the terms of the award is a notable omission, and, if unrectified, will effectually preclude me from accepting the honour for which I have been designated by the Council."

Three days later Wilde wrote again to suggest a wording which he would consider satisfactory. In the meantime the proposed conferment of the medal in the original terms had been published in the daily press; this resulted in a lawyer's letter, and the issue of a writ to restrain the Society of Arts from announcing the award in their own journal before some agreement had been arrived at as to the wording. The Society then altered the wording. It added a sentence referring to Wilde's application of his machine to search-lights and the electro-deposition of metals; and with regard to the dynamo machine, it added that the principle which formed the basis of Wilde's work is "now used in all dynamo machines." This was a fair and adequate statement, but it displeased Wilde more than ever. I think, however—and I saw much of him at that time—that he was more amused than vexed when the Society sent him the medal by post instead of following their usual practice of presenting it at their annual meeting under the presidency of the Prince of Wales.

The incident ended with a letter addressed by Wilde to the Institution of Electrical Engineers, in which, after declaring his dissatisfaction with the terms under

which the medal had been bestowed upon him by the Royal Society of Arts, he proceeds:

"Nevertheless, the action of the Society has invested the Albert Medal of 1900 with a considerable degree of historical interest, and, in response to the recent invitation of the Council of the Institution for gifts of such objects to form a permanent Museum, I enclose herewith the Medal as a contribution to the collection."

The whole correspondence was afterwards published and freely circulated by Wilde.

One of Wilde's peculiarities was his strong objection to have his photograph taken, which was a pity, because he really had a fine and expressive face. "I want to be remembered by my works and not by my physiognomy," he often told me. He added that on one occasion he gave way to the wishes of his wife, but having repented he had the plate destroyed. A copy, however, seems to have been kept by the photographer and was reproduced in his obituary notice. I cannot help regretting this disregard of his wishes

It remains to mention his extensive benefactions. He gave altogether 10,000*l.* to the Manchester Literary and Philosophical Society and 5500*l.* to the Académie des Sciences of Paris. His endowments, during his life, of scholarships and readerships at Oxford amounted to 3000*l.*, and a contribution of 1500*l* to the Benevolent Fund of the Institution of Electrical Engineers raised the total of these gifts to 30,000*l* Yet he died a comparatively poor man The residuary estate, which was bequeathed to the University of Oxford, after deducting some minor legacies, only amounted to 10,000*l.*

I am afraid that this account dwells a good deal on Wilde's pugnacious peculiarities, but in spite of many acute differences of opinion, I had a very high regard for his straightforward character and attainments. We always remained friends.

The Phylogenetic Classification of Flowering Plants.[1]

By JOHN PARKIN.

THOUGH "the abominable mystery," as Darwin called the problem of the origin of Flowering Plants, is by no means solved, there has been before the botanical world for some years a theory of their origin which is consonant with the derivation of all forms of existing flowers from the Ranalean type. Through Wieland's brilliant elucidation of the structure of the fossil Bennettitean fructification at the beginning of this century, botanists became acquainted for the first time with an unexpected bisexual seed-bearing cone, in which the two kinds of sporophylls bore the same relative position to one another on the axis as they (the stamens and carpels) *invariably* do in the angiospermous hermaphrodite flower; and further, such a cone was subtended by a number of bracts resembling a perianth. The temptation naturally was great to suggest a real bond of affinity between the Flowering Plants and these Cycadean-like Mesozoic plants, the Bennettitales (Cycadeoideæ). A theory was worked out to this effect. Though the peculiar nature of the female part of the cone precludes the direct origin of the Angiosperms from the Bennettitales, the view was put forward that the two groups had diverged from common ancestors with a generalised type of flower-like cone—the *anthostrobilus*, as it was called. These ancestors, it was thought, probably arose from the seed-ferns (Pteridosperms). It was further conjectured that the Angiosperms owed their being to the substitution of insect-pollination (entomophily) for wind-pollination (anemophily), and it has even been hazarded later that this type of cone, the anthostrobilus, may have been evolved in response to insect-visitation. The theory also provided a resting-place for that small puzzling group of Gymnosperms, the Gnetales, and accounts for the peculiar male (morphologically hermaphrodite) "flower" of Welwitschia — the stumbling-block to those botanists who endeavour to derive the Gnetales from the Conifers, a group characterised as a whole by possessing unisexual cones.

The whole speculation, which has rightly or wrongly been termed the "strobilus theory of angiospermous descent," still awaits confirmation or refutation. It has with some botanists lost favour on general grounds. The recent discoveries of palæobotany show that many of the main groups of vascular land plants can be traced right back to Devonian times as independent lines, and Dr. A. H. Church in a recent stimulating memoir has speculated as to the possibility of these main phyla having been even differentiated in the sea independently from one another. Thus it is just possible that the Angiosperms may represent such an independent line, originating from a distinct group of Algæ. Their resemblance then to the Bennettitales would become merely an interesting parallelism. This then may be said to be the chief criticism that can as yet be levelled against the strobilus theory. Dr. Scott, in his latest edition of his "Studies in Fossil Botany," sums up in favour of the theory.[2] If the Angiosperms throughout the ages have been independent of any other vascular group, one wonders why obvious traces of them have never come to light in the Palæozoic rocks. It is difficult to believe that they can, as it were, have stepped out of the sea, fully differentiated, in late Mesozoic times. One of the astonishing facts of palæobotany has been the sudden appearance of Flowering Plants in late Cretaceous times. Dicotyledonous stems are now known, however, from lower Cretaceous rocks, and recently Mr. Hamshaw Thomas has brought to light some remarkable fossil fruits (the Caytoniales), resembling those of Angiosperms, from the middle Jurassic. Possibly then ere long some fresh light may be thrown on the problem.

It is important to recognise that the classification of Angiosperms based on the Ranalean families does not stand or fall with the Bennettitalean theory. If the latter be disproved, the former is only affected to the extent that it has no fossil group upon which to fall back. All modifications of the flower can still as before be derived from a magnolia-like one. The Bennettitalean theory has helped to focus the attention

[1] Continued from p. 342.

[2] 3rd edit. vol. 2, London, 1923, pp 427-430

of botanists on the Ranales. Once they have grasped the possibilities of making this group of families a basis upon which to found a new system of classification, they will not be likely to return to the Englerian view of the primitive flower, should the theory have eventually to be discarded. In this way it will have served a useful purpose.

In recent times certain botanists, notably Bessey of America and Hallier of Holland, have endeavoured to supersede Engler's classification by introducing systems of their own based on the Ranalean families. Hallier was perhaps too changeable and prolix to attract the attention he deserved. Bessey was more thorough and logical. The writings of both suggest, however, that their attempts at new systems were more the outcome of book-work than of the actual examination of the living or dried specimens. It is otherwise with Hutchinson. He has not only at hand an unrivalled collection of plants, but also has behind him some twenty years' experience of comparative work in this line. In his first "Contribution" he sets forth his principles,[3] which are essentially those of Bessey, and, we surmise, they will be generally acceptable to those botanists who have ceased to believe in the primitive character of the amentiferous flower. He points out that the evolution of the flower among existing Angiosperms has taken, broadly speaking, either an upwards or downwards course. This in terms of function may be interpreted as either greater adaptation for insect-pollination or a change-over from entomophily to anemophily: and in terms of structure as either great modification and advancement in the shape of the corolla or the complete loss of this organ as no longer required for insect-attraction.

These two evolutionary changes may be considered to have been continually in action in the past and to be still in operation The older the petalous (entomophilous) group, the more apetalous (wind-pollinated) forms will it have given off This is exemplified by the fact that the Apetalæ (in the taxonomic sense) have probably been derived as a whole from the Polypetalæ (petals free), a group generally considered earlier and more primitive than the Sympetalæ (petals united). These latter, of mixed polypetalous ancestry and in most cases highly specialised for insect-visitors, present few anemophilous forms. The plantains (Plantaginaceæ) and our native ash (*Fraxinus excelsior*) alone come to one's mind. In the former the corolla has not actually disappeared, though scarcely functional. The latter has naked and often unisexual flowers, though certain species of this genus and the rest of the family (Oleaceæ) have hermaphrodite flowers with a corolla. Perhaps Englerians would have held the flower of the ash as primitive if it had stood alone. As it is, no botanist doubts but that this tree has had petal-bearing entomophilous ancestors.

The paucity of apetalous derivatives from the Sympetalæ may be considered to be due to the shortness of geological time since these forms appeared. At the same time it is well to bear in mind the possibility that the more highly specialised for entomophily a flower becomes, the more difficult it may be for it to change over to anemophily. Hutchinson uses these ideas of progressive and retrogressive evolution as applied to the flower in his proposed scheme for the rearrangement of the earlier dicotyledonous families (Archichlamydeæ). So far as possible, in any circle of affinity, after fixing on the basal group, he first treats of the families showing corolla-advancement, *i.e.* those increasingly adapted for entomophily; and then the families showing corolla-reduction, *i.e.* the degraded forms which through force of circumstances have had to take to anemophily.

A restrictive attitude is adopted by Hutchinson in respect to the value given to the various grades of classification, such as order,[4] family, and genus. The groups thereby become more natural and less unwieldy. An example will illustrate his mode of procedure. Engler's old cohort, Ranales, comprising about 15 families, is split into five orders—the Magnoliales, Anonales, Laurales, Ranales, and Berberidales. His Magnoliales embrace practically the genera contained in the old family, the Magnoliaceæ. This he breaks up into three families—the Magnoliaceæ, Winteraceæ[5] (Drimys and its associates), and Schizandraceæ. The Magnoliaceæ now becomes a very natural family, composed of the genera Magnolia, Michelia and their close allies, together with the Tulip-tree (Liriodendron). The Ranales in the restricted sense contain the Ranunculaceæ (unaltered in composition, but its taxonomy improved upon that occurring in the "Pflanzenfamilien"), the Nymphæaceæ and the Cabombaceæ, formerly a tribe of the foregoing but now raised to family rank.

In some ways we regret the use of Ranales in this restricted sense, though it is in accordance with taxonomic rules. This term and its adjectival form, Ranalean, have been employed in recent times in the wide sense, and especially with respect to the Magnolian flower, hence confusion may be apt to arise in the near future. This, of course, can be avoided by strictly defining one's terms. A new embracing term is now wanted for the families composing, say, the old Ranales together with the Dilleniaceæ. Might not also a substitute be found for the clumsy term, Archichlamydeæ—one in keeping with Sympetalæ, which Hutchinson apparently intends to use instead of Metachlamydeæ? The revival of the Choripetalæ of Eichler is a possible suggestion.

The view that the tree preceded the herb is one that has made headway in recent years. The reverse was perhaps vaguely held last century. Hutchinson makes full use of this new idea, though at the same time prepared to recognise that here and there the opposite may have taken place, namely, herbs giving rise to woody forms. He thinks, for example, that both Clematis and Berberis have had a herbaceous origin. This is distinctly interesting to plant anatomists. It may be expected that the wood of shrubs and trees evolved from herbs will show structural features distinct from the wood of trees which have come from ancestors primitively arboreal in habit. In his proposed rearrangement of the Archichlamydeæ he shows graphically by means of a phylogenetic tree[6] the possibility of

[3] *Kew Bulletin*, 1923, p. 73.

[4] To the older field botanists familiar with the term, *natural order*, now superseded by that of *family*, the use of *order* in this wider sense may be confusing. It was adopted in place of *cohort* by the International Botanical Congress of Vienna, 1905. Presumably there were strong reasons for this change, but they are not apparent to the present writer.

[5] *Kew Bulletin*, 1921, p. 165.

[6] *Kew Bulletin*, 1924, p. 128.

deriving this assemblage of families as two distinct branches—one from the tree Magnoliales and the other from the herbaceous Ranales. Each branch in its ramifications is depicted as giving its quota to the "Apetalæ," the tree-line supplying chiefly the Amentiferæ, and the herb-line such alliances as the peppers, docks, and chenopods. In one case the arborescent habit continues dominant, though herbs eventually arise in the highest forms, *e.g.* in the Papilionaceæ; in the other case herbs prevail, though shrubs and trees occasionally make their appearance. This novel and suggestive idea requires thorough sifting to see how far it may be considered sound. In this connexion, we may here point to his treatment of the family, Saxifragaceæ, as defined in the "Genera Plantarum" and "Pflanzenfamilien." Most will admit that this family, as at present constituted, is cumbersome and unnatural. Hutchinson brings his tree-herb speculation to bear upon it and cleaves it in two. The herbaceous Saxifrages and their allies are placed along with the Crassulaceæ in the order Saxifragales, derived directly from the Ranales (in the strict sense); while the remainder of the old family—the bulk of it, in fact—is split into the Escalloniaceæ, Grossulariaceæ, and Hydrangeaceæ, and as such compose part of his new order, the Cunoniales, derived directly from the arborescent Dilleniales. In consequence, the old family is separated into two sections placed far apart. In this connexion one would like to know how he views the hitherto supposed relationship between Spiræa and Astilbe. If he still recognises it, then no provision appears to be made for it in his scheme. He derives the Rosaceæ, and presumably the genus Spiræa, from the woody Dilleniales; whereas the Saxifragaceæ, as he now limits the family, to which Astilbe should naturally belong, are obtained from the herbaceous Ranales. He partly saves himself in a footnote [1] as follows: "It is probable that some herbaceous *Rosaceæ* have not had a common origin with their ligneous associates." But among the Spiræas are many ligneous forms. These will still require explaining.

In conclusion, it may be thought that the introduction of a new classification of Flowering Plants is a task of too great importance to be entrusted to a single individual. Some may hold it to be a matter for a body of experts. Taxonomy, however, in the past has not progressed in this way. Systems have largely been the result of individual effort. Some have become authoritative, others have not. A single mind tends to keep throughout a consistent value for the various grades of classification. The whole effort will show on completion a symmetry and balance which it otherwise would not possess. This is far from saying that a new system should not be subjected to searching criticism while it is yet in the process of elaboration.

Obituary.

RIGHT HON. SIR CLIFFORD ALLBUTT, K.C.B., F.R.S.

THE sudden and quite unexpected death, after a few minutes' distress, early on the morning of February 22, of Sir Clifford Allbutt, Regius professor of physic at Cambridge since 1892, robs British medicine of its acknowledged leader, who from his scholarly accomplishments recalls Samuel Johnson's description of William Heberden the elder (1710-1801) as "Ultimus Romanorum, the last of the learned physicians." He was indeed remarkable for his wide knowledge not only of modern but of ancient medicine, and for the broad horizon of his conception of the relations of medicine and how its future course should be directed. Thus he was ever insistent on the importance of a sound general educational basis on which medical studies should be engrafted, and he held strongly that universities should provide a liberal education and not lay themselves out for the more utilitarian qualification for the practice of any art or trade, and should not compete with hospital schools. His high standard was shown in a work—the result of many years' research—on "Greek Medicine in Rome" (1921). Since 1888 he had advocated the necessity for the study of comparative medicine and pathology, and happily he lived to see his own University start an Institute for this branch of research, and appropriately he was the first president of the Section of Comparative Medicine at the Royal Society of Medicine.

The wisdom of Allbutt's selection as Regius professor of physic in 1892, and of the departure from the existing custom of appointing a resident physician, has been signally justified. By a similar change at Oxford in 1905, by which Sir (then Dr.) William Osler was transplanted from the Johns Hopkins Hospital, Baltimore, the two older universities were represented by a pair of Regius professors with a world-wide reputation, such as had never before fallen to their lot, for clinical experience and scientific attainments. There were, indeed, some curious coincidences in the lives of these two friends: they became members (1878) and fellows (1883) of the Royal College of Physicians in the same years, gave the Goulstonian Lectures in successive years, and, though these are the almost natural duties of such Regius professors, delivered the Harveian Oration at the College, and edited successful "Systems of Medicine" which have gone through two editions and are destined for a third in the near future by other hands.

Thomas Clifford Allbutt, the son of the Rev. Thomas Allbutt, Vicar of Dewsbury in Yorkshire and friend of Charles Waterton the naturalist, was born on July 20, 1836, and was named Clifford after his godfather, an artist, who married his father's sister, and whose son Edward Clifford painted the portrait of Lady Allbutt hanging in his study at St. Radegund's, Cambridge. Before the Allbutts' time, Patrick Brontë had been one of the curates at Dewsbury, and they knew his famous daughters well; Sir Clifford regarded it as a sacred duty to contradict the impression given in Mrs. Gaskell's Life of Charlotte Brontë that the family were isolated and not in touch with the country people.

Educated at St. Peter's School, York, he went up in 1856 as a classical scholar to Gonville and Caius College, Cambridge, and his name was the only one in the first class of the Natural Science Tripos for 1860 with distinc-

tion in chemistry and geology. Entering on November 5, 1858, as University students then usually did, the Medical School of St. George's Hospital, and while a clinical clerk for Dr H. Bence Jones, F.R.S., secretary of the Royal Institution and an ardent chemist, he became interested in acute aortitis, a subject which afterwards much engaged his attention in connexion with his view of the causation of angina pectoris. With Lockhart Clarke, who was then working at the hospital, he was on friendly terms, and was influenced by his microscopical investigation of the central nervous system, while to J. W. Ogle he ascribed the stimulus to apply the ophthalmoscope to general medicine. He took the M.B., Cambridge, so early as 1860 and the M.D. eight years later. After leaving St. George's he spent some time in Paris following the teaching of the great Trousseau, and about 1862 settled down to practice in Leeds, where he was attached to the Royal Infirmary (1864–1884), and had a most extensive consulting practice in Yorkshire and the North of England, while at the same time carrying out much research and literary work.

In 1889 Allbutt left Leeds for London on accepting a Commissionership in Lunacy, and thus became associated again with Sir James Crichton-Browne, with whom he had worked at the West Riding Asylum; but his stay in London was cut short in 1892 when, after first refusing, he was persuaded to succeed Sir George Paget as Regius professor of physic in the University of Cambridge. For the remaining thirty-two years of his extremely active life, though taking a prominent part in the medical activities of the University and of the country in general, sitting on commissions and numerous committees, he was no longer driven by the exigencies of a busy consulting practice, and thus spare time he utilised to the full and to the great advantage of his medical brethren. A notable service in this respect was the editing of a "System of Medicine" (1896–1899) in eight volumes, which was the lineal successor to the "System of Medicine" (1866–1879) in five volumes edited by Sir J. Russell Reynolds. Allbutt's "System" passed into a second edition (1905–1911) in eleven volumes, and received a well-deserved welcome from the medical profession.

It is difficult to summarise Sir Clifford's contributions to medicine, for in addition to his philosophically minded addresses and historical work, he ranged far and wide over the province of medicine. But his name will be more especially connected with certain advances, in the first place, he did much to introduce the now general use of some instrumental methods in medicine, thus in 1868 he introduced the present form of clinical thermometer in place of the long and unwieldy one previously available, and made many observations on the temperature of the body in health and disease, reading a paper in 1873 on the effect of exercise on the bodily temperature to the Royal Society, of which he was elected a fellow in 1880, and was subsequently councillor for two sessions and vice-president.

In 1871 there appeared Allbutt's epoch-making work, "The Use of the Ophthalmoscope in Diseases of the Nervous System and of the Kidneys, and also in certain other General Diseases," which, in addition to giving his own extensive experience, covered the literature, as his published work always did, in an admirably complete manner. It is worth noting that this monograph appeared in the year of the death of the original inventor of the ophthalmoscope—Charles Babbage (1792–1871)—and that its practical use, and of Helmholtz's later modification, in medicine, though suggested by Sir Spencer Wells, is largely due to the advocacy of Allbutt and of Hughlings Jackson. He also did much to bring in the now familiar use of the stomach tube and the sphygmomanometer for the estimation of blood pressure.

Allbutt's most consistent work was on diseases of the cardio-vascular system; in 1868 he gave one, if not the first, of the descriptions of syphilitic disease of the cerebral arteries, buried in the now extinct St. George's Hospital Reports; two years later he insisted on the effects of overwork and strain on the heart and great vessels, published in the same series; since 1895 he had described hyperpiesia or high blood pressure of obscure origin, and insisted that it was not secondary to arterial disease or necessarily to nephritis. Angina pectoris has been variously explained, the most popular view being that it is due to disease of the coronary arteries of the heart, but since 1894 he argued that its real cause is disease of the first part of the aorta. His observations on these various subjects were collected in 1915 in his "Diseases of the Arteries, including Angina Pectoris" (2 volumes, Macmillan), and there is in the press a supplementary work on "Arteriosclerosis: A Summary View." Though he wrote much, he did so with a very critical and careful eye, and, as mentioned in his "Notes on the Composition of Scientific Papers," now in a third edition, he usually made four drafts at least before the manuscript was ready for the printers. The finished charm of his writings aptly corresponded to his personality.

A wide reader, he was most generous in recognising good work by unknown men, and though advanced in years always maintained the mental elasticity of youth. This was, indeed, in keeping with his physical activity; for, like his friend the late Sir Hermann Weber, he was until well on in years a keen Alpine climber; as he wrote to the *Times* a week or so before his death about the proposed alteration, artistically for the worse, of the bridge over the Rotha's "living wave" at Grasmere, he had walked in the Lake District almost every year since he was fourteen, and he rode a bicycle or tricycle last year. With a now somewhat old-fashioned courtesy he was independent, and on occasion spoke out vigorously against what he thought wrong; for example, his castigation of the practices of some gynæcologists in his "Visceral Neuroses" (1884), and more recently his disapproval of psycho-analysis. What would be eagerly sought as honours by many men came by natural right to this beloved physician, and deservedly the list is too long to detail. They were accepted with pleasant expressions of modesty and appreciation, but it could not but be felt that the givers of honorary degrees and medals really honoured themselves by their award. He was made K.C.B. in 1907, and a Privy Councillor in 1920, and could, had he desired it, have been made a peer. English-speaking medicine can well be proud of its great and broad-minded leader.

HUMPHRY ROLLESTON.

THE death is announced from America of Dr. Joseph Clark Hoppin, the well-known classical archæologist. Dr. Hoppin was a graduate of Harvard University, and at one time was professor of classical archæology in Bryn Mawr College, Philadelphia, but relinquished this post to devote himself to research. He was a student at the American School of Archæology at Athens in 1892-3, and took part in the excavations carried on in the Argive Heræum between the years 1892 and 1895. When the work of excavation came to an end, he took charge of the Department of Ceramics and was responsible for the examination and classification of the large quantity of pottery in the Museum at Athens which had been obtained from the Heræum site His "Handbook of Attic Red-Figured Vases," a standard authority, appeared a few years ago, and his book on "Greek Black Figured Vases" appeared only at the end of last year He had devoted himself for many years to the formation of a collection of classical antiquities, and it is said that his collection was perhaps the most complete of any in private hands in the United States The value of his work had been recognised in Great Britain by election to honorary membership of the Society for the Promotion of Hellenic Studies, an honour which he greatly appreciated. According to a sympathetic notice by one of his former colleagues in Athens, which appeared in the *Times* of February 4, he had projected further excavations, at his own expense, shortly before his illness, in the Argive Heræum.

THE *Chemiker Zeitung* records in a recent issue the life and work of Dr. Richard Escales, who died on September 9 at Munich. Dr Escales' name will be remembered chiefly in connexion with his work on explosives He was born on July 8, 1863, at Zweibrücken, where his father owned a textile factory. After studying at Würzburg, Munich, Erlangen, and Zurich, he graduated in 1886, and for a while was engaged in his father's business. Somewhat later he returned to Munich in order to undertake the study of explosives in the laboratory of Adolph von Baeyer, and in 1898 he discovered *ammonal*, a high explosive containing aluminium powder, which played a prominent part in the War. He sold the patent rights of this discovery for an inconsiderable sum in Vienna In 1902 he founded an experimental station for explosives at Munich, where during the War he acted as director of the department of "Minenwerfer." He compiled a seven-volume standard work on explosives and was the founder and publisher of the *Zeitschrift fur das gesamte Schiess- und Sprengstoffwesen*.

WE regret to announce the following deaths

Dr J Cleland, F.R.S., from 1877 until 1909 professor of anatomy in the University of Glasgow, and afterwards emeritus professor, on March 5, aged eighty-nine.

Dr Willet G Miller, provincial geologist of Ontario, known for his work on the pre-Cambrian and economic geology of Ontario, on February 5, aged fifty-eight

Dr J A Ormerod, registrar since 1909 of the Royal College of Physicians, and Harveian Orator in 1908 and Lumleian Lecturer in 1914 of the College, on March 5, aged seventy-six

Sir William Peck, Director of the Edinburgh City Observatory, Calton Hill, on March 7, aged sixty-three.

Dr J Ward, professor of mental philosophy and logic in the University of Cambridge since 1897, on March 4, aged eighty-two

Current Topics and Events.

MUCH satisfaction is felt in scientific circles that the Prince of Wales has consented to occupy the presidential chair of the British Association for the meeting to be held at Oxford next year, either from July 28 to August 4, or from August 4 to August 11 At a meeting of the General Committee of the Association on Friday, March 6, Sir Ernest Rutherford, who was in the chair, reported that the Prince had intimated his willingness to accept the presidency, and he was, therefore, nominated by the Council to the Committee and elected unanimously. The Prince Consort was president of the Association for the meeting held at Aberdeen in 1859, but since then no other member of the Royal Family has filled that office. British science is greatly honoured by the consent of the Prince of Wales to act as president, and his knowledge of the resources and needs of the Empire is so extensive that whatever he may say in his address at the Oxford meeting will have wide influence upon both science and the community.

A PAPER by Sir Arthur Schuster, "On the Life Statistics of Fellows of the Royal Society," has just appeared in the Proceedings, and at last week's meeting of the Society the author himself gave an interesting summary of conclusions. Previously, the subject had been studied by General Strachey, who, in 1892, communicated a paper based on a statistical examination of the average age of the 15 fellows annually elected, their probable duration of life, relationship to an eventual maximum strength of fellowship, and other considerations The point whether or not a small increase in the number of annual elections is required, in view of the larger scientific output of the country, has been discussed in recent years, but without bringing any change of procedure The number of fellows of the Society at the beginning of 1848, when new statutes came in force, was 768 In consequence of the restriction in the number annually elected, this total was diminished by more than a hundred in the first ten years, by 1912 the maximum had become 455 Since then the numbers show a steady decline On January 1, 1923, there were 439 fellows As regards age at election, Sir Arthur remarks that it is difficult to gauge the effect of the War, but probably it was appreciable. His impression is that the younger men were kept back in their scientific work even when they were not actually in the field; while some of maturer age were substantially assisted in obtaining the fellowship by their War work The youngest man elected into the Society since 1847 was John Lubbock (afterwards Lord Avebury), who entered at the age of twenty-four.

BROADCASTING in Great Britain on a regular and commercial basis started at Marconi House in London in November 1922. The aerial work of the new 2 LO station has been erected on the roof of the Selfridge building in Oxford Street. There are two towers of the lattice type, the top of each being about 250 feet above the roadway. The towers are entirely self-supporting, no guy wires being used. The aerial is of the two-wire type, the distance between the wires being 15 feet, the wires being connected to an insulator on the roof of the apparatus room by two large cage connectors The aerials are made of nineteen strands of No 16 bronze wire and are very heavy. Strings of eight shackle insulators serve to spread and anchor the leading-in cages The machines installed in the power-house are direct coupled motor generator sets running from the supply mains Eighteen kilowatts is taken from the mains Some of this power is needed for the master oscillators which maintain the frequency of the carrier wave perfectly constant. A certain amount of power also is required for the filaments of the many oscillating, modulating and rectifying valves, as well as for the ordinary losses in the machines The amount of power radiated into space is about three kilowatts, and this is the rating of the station The greatly increased power and the greater size and height of the aerial will more than double the range of the present 2 LO broadcasting station The studio, which has always been entirely distinct from the transmitting apparatus, will remain at the B B C headquarters at Savoy Hill, W C.2. As before, it will be connected with the transmitter by special underground cables The new station will shortly be in regular operation, for the experiments already made have proved extremely satisfactory It will be one of the finest broadcasting stations in the world

SIR ARTHUR KEITH, in his discourse at the Royal Institution on Friday evening, March 6, concerning the rate of man's evolution, described the difficulties in the study of this subject due to the varying stature of men and women among all races of mankind, entailing the measurement of many thousand individuals. In searching the ancient burial-places of England, it is found that the people buried in ancient tombs differed in height in the same manner as at the present time It may be said that there has been no great change in the stature of the inhabitants of these islands since the close of the Ice Age The mean average of the modern Englishman of 5 feet 6 inches may be taken as the pivot on which the scales of stature have been balanced for thousands of years. This was shown from a study of fifty ancient skulls from English graves carried out in 1914–15 The evidence obtained from certain fossil remains discovered at Galley Hill in 1888 points to an antiquity of man of no less than 100,000 years. The facts which have been accumulating for some years past on the continent of Europe confirm this conclusion. The discovery of fossil remains made in South Rhodesia in 1921 has disclosed a more primitive human type, but its age has not yet been definitely fixed By studying the facts which arise from the discoveries made in various parts of the world, anthropologists are able to form an opinion as to the rate at which man has come by the present characters of his body and brain; and the evidence which has been accumulating leads them to the conclusion that the evolution of man has been more rapid than many have hitherto believed

THE China Indemnity (Application) Bill passed its second reading in the House of Commons on March 3 without a division, and was referred to a standing committee of the House. The debate was interesting and informing, and as such contrasted favourably with the second reading of the Bill brought in last May by the late administration Mr McNeill's accurate and well-marshalled knowledge of the facts, and his conciliatory attitude, made an admirable impression not only on the opposition, who objected to the changes in personnel made in the contemplated advisory committee, the places of Mr Bertrand Russell and Mr Lowes Dickinson being taken by Prof Southill and a business representative, but also on the members of his own party, who contended that the best expenditure of the fund would be on railways Mr MacDonald in a convincing speech made short work of this contention, while admitting the value of railways in developing national resources He urged that, in this case, the insufficiency of the sums available; the troubles, complexities, and negotiations which would be involved even in capitalising the fund for such purpose, and the psychological effect on the Chinese of so using the fund rendered such a project impracticable.

IN Mr McNeill's opinion the phrase in the China Indemnity (Application) Bill "educational or other," which describes the purposes of the fund, should be interpreted to mean that the object must be something in the nature of education, or, at all events, it must be something which is not absolutely divergent from the main idea. Since, however, notwithstanding this opinion, divergent purposes were pressed on the House, this point, with Mr McNeill's concurrence, will be decided in the standing committee. It may be hoped, therefore, that Mr Somerville's amendment, "educational, medical or other similar purposes," will be accepted These words evidently meet the views which Mr McNeill expressed, and their adoption would relieve the advisory committee of an invidious task As to the constitution of this committee, a present member of it characterised it as "derisory" from a Chinese point of view. Though its object is educational, the Board of Education has no concern whatever in its membership, no medical man has a seat; and, if trade interests are not to be pressed, the inclusion of a Board of Trade official seems undesirable. Besides that, the other members are so occupied with public or private work that the time and attention they would be able to devote to this important work must be limited, and, considering the opportunity of national service which the fund offers, may be exiguous.

THE report of the executive committee of the Empire Cotton Growing Corporation, submitted at the

meeting of the administrative council held on February 25, has underlying it a tone of expectation of a great increase in cotton production in the tropical and subtropical colonies Indeed, many signs point in this direction, and it is a matter of vital importance to the British Empire to grow as much of its own cotton as possible Mr Milligan, formerly Inspector-General of Agriculture in India, and now in charge of the work of the Corporation in South Africa, gives an interesting account of this There will be fifteen men working at cotton problems this year, as against four in 1924. Rhodesia, where the greatest possible interest is being taken in cotton, has so rapidly expanded its area under this crop that difficulties are arising in respect to ginnery accommodation Nigeria is about to start Government farms for the supply of seed The Corporation has appointed a cotton breeder to work in the Sudan. Nyasaland has obtained a reduction in railway rates upon maize, which will form the necessary secondary crop for a rotation, and so on The evidence of the great interest now being taken in Empire cotton, and of the expansion of its cultivation, is growing more marked every day

COL. PURVES, the Engineer-in-Chief of the Post Office, read an interesting paper to the Institution of Electrical Engineers on the "Post Office and Automatic Telephony" on March 5 A general history was given of the development of automatic exchanges The system actually adopted by the Post Office is a development of the Strowger system, now called the "Director System" This system was devised by the Automatic Telephone Manufacturing Co of Chicago, and, on the whole, it was considered better than the other systems. The electric power required for an exchange of 10,000 lines is provided by two 50-volt batteries each of 10,000 ampere-hour capacity The requisite current at peak load will exceed 2500 amperes When a subscriber has finished dialling his instrument he hears immediately the "ringing tone" which tells him that the required subscriber is being rung up, or the "busy tone" which tells him that he is engaged. The extreme complexity of modern automatic circuits and equipment is illustrated by the fact that a single automatic switching unit of 10,000 lines comprises no less than 5 million contacts. Any one subscriber in an exchange of this size can obtain connexion with any other subscriber by 240,000 different linkages. To reach all the subscribers in his unit he has 2400 million different linkages at his disposal. When we consider the large number of other exchanges he can get in contact with, the number of linkages is enormously increased. Graduated courses of instruction are now being given to the skilled workmen who will maintain the exchanges in working order. The inspectors and engineers who will have to be responsible for the mechanism and the efficiency of the service are also being specially trained.

COL. PURVES, in his paper referred to above, points out that the modern automatic calling dial is a remarkably simple piece of apparatus considering the immense complexity of the machine which it controls This simplicity is the result of a long period of evolution since some one in the Automatic Electric Co first had the happy thought of making a rotating disc with finger holes for the purpose of sending the trains of impulses required for the Strowger automatic system. The master patent secured a monopoly for this device from 1898 to 1912 During this time a great amount of ingenuity was expended in inventing other signalling devices which would not infringe this patent During all this period an old and forgotten telegraph device, invented by Cooke and Wheatstone not later than 1839, anticipated in all essential respects the terms of the master patent It was found during a clearing up of an old storeroom of the General Post Office in 1913, when the master patent had just expired It anticipated all the explicit claims of this patent. It is curious that a patent controlling such large commercial interests, and considered unassailable for fourteen years, should have been so completely anticipated by the earliest pioneers of telegraphy.

D N. PRIANISHNIKOV, the eminent Russian professor of agriculture, whose thirtieth anniversary of his scientific work is being celebrated in Moscow during this month, was born in 1865 in Kiachta, S.E Siberia After completing his course at the school at Irkutsk he entered the University of Moscow, but soon left it to take up studies in the Agricultural Academy at Petrovskoje, near Moscow, in 1888 he passed his final examinations, and was offered a post-graduate scholarship In 1891 he was sent abroad to study the agricultural chemistry and physiology of plants, mainly in Germany, with Prof. Schulze In 1891 he was appointed lecturer, and in 1895 professor of agriculture in the Agricultural Academy of Petrovskoje, a post which he still holds, so that through his laboratories passed many hundreds of Russian agricultural specialists. In his scientific work Prof Prianishnikov approaches the views and ideas of Bussengo, while his thorough training in the physiology of plants by one of the ablest botanists of the last century, K Timirjazev, and in chemistry by G Gustavson, enabled him to elucidate a long series of most complicated problems, mainly concerning fertilisers and manures and their physiological effects His dissertation for the doctor's degree, on the dissimilation of proteins in connexion with breathing and assimilation of carbon dioxide, which appeared in 1899, has been followed by numerous other works, about 200 in number, mainly in Russian and German agricultural periodicals. Two of his books, a course of agriculture, and a handbook on fertilisers and manures, are amongst the best of their kind, the latter having been translated into Polish and German The influence of Prof. Prianishnikov's works and of his teaching on the progress, especially of research work, in Russian agriculture cannot be overestimated Hundreds of his former pupils, with whom he always keeps in touch, have been and still are working in different parts of Russia, developing his ideas and accumulating scientific data. For an agricultural country like Russia, scientific workers

of Prof. Prianishnikov's type must be (if not always are) considered amongst the principal factors in the progress of the country.

In the official report, issued by the Textile Institute, of Proceedings of the first Empire Textile Conference (held at the British Empire Exhibition at Wembley in Whit-week 1924) accounts are given by the Directors of the Cotton, Woollen, and Linen Research Associations of the present position of scientific research in textiles and of the advantages that must necessarily follow from persistent application of scientific method to problems of the trade Numerous examples are given of spinning, weaving, and finishing problems which are now being investigated by the research associations, and attention is directed to the unlimited field for further research on matters the solution of which will be of the utmost national and Imperial importance from the points of view of the grower of the raw material, the manufacturer and the user In addition, the first part of the report contains sixteen papers dealing with exceedingly wide interests, including Empire supplies and consumption of wool and cotton, the possibilities of the British silk trade and the statistics of the textile export trade. It is pointed out that the rapid increase in wool consumption during the last twenty years has been accompanied by an enormous decline in wool production, and an appeal is made to our great overseas Dominions to rectify this lack of proportion. The vast economic importance of the cotton trade is referred to, and it is emphasised that as this is the largest manufacturing industry in Great Britain, the importance of increased Empire production of raw cotton, upon which the stability of this great industry must ultimately depend, is a matter of grave concern if the trade is to retain its pre-eminent position in the world's markets The decline of the British silk trade in the last fifty years has been considerable, although the Empire demand is sufficient to warrant a four-fold expansion of British trade in this material. The second part of the report contains eleven scientific papers on the physical and physico-chemical problems relating to textile fibres, and a discussion thereon (held in conjunction with the Faraday Society), an account of which appeared in NATURE for July 5, 1924, p 27

The Faraday Medal of the Institution of Electrical Engineers will be presented to Sir J. J Thomson at the ordinary meeting of the Institution to be held on Thursday, March 19, at 6 P M. The presentation will precede the reading of Mr S. Evershed's paper on "Permanent Magnets in Theory and Practice"

The Society of Glass Technology has established a small Research Fund for the purpose of promoting research in subjects related to glass technology. Grants from this fund will be made to assist in conducting specified items of research approved by the Council of the Society Applications should be addressed to the Secretary, Society of Glass Technology, Darnall Road, Sheffield

The annual prize of the American Association for the Advancement of Science for the 1924 meeting at Washington has been divided and awarded as two prizes of five hundred dollars each, to Dr. L. R. Cleveland, of the Johns Hopkins School of Hygiene and Public Health, for his work on the physiology of termites and their parasites, and to Dr. Edwin P. Hubble, of the Mount Wilson Solar Observatory, for his work on the nebulæ.

The Hon. W. G. A Ormsby-Gore, M P., Under-Secretary of State for the Colonies; Sir Frank Heath, Secretary of the Department of Scientific and Industrial Research; and Sir Richard Gregory will be the principal guests at the annual dinner of the National Union of Scientific Workers to be held at the Adelaide Gallery (Gatti's Restaurant), King William Street, Charing Cross, on Thursday, March 19 The president of the Union, Prof. G. H Hardy, will be in the chair

The Fison Memorial Lectures, which have been established in memory of the late Dr. A H Fison, lecturer in physics at Guy's Hospital Medical School, and Secretary of the Gilchrist Educational Trust, will be inaugurated on Thursday, May 7, when the first lecture will be given by Sir J. J Thomson, Master of Trinity College, Cambridge, who will take as his subject, "The Structure of Light" The Right Hon. The Earl of Balfour will preside at the meeting.

The Huxley Medal of the Royal Anthropological Institute has been awarded to Sir William Ridgeway, Disney professor of archæology in the University of Cambridge, in recognition of his services to anthropological science, particularly in connexion with the study of the archæology of the Mediterranean area. Sir William Ridgeway, who was president of the Royal Anthropological Institute in 1908 and 1909, will deliver the Huxley Memorial Lecture in 1926. The Huxley Memorial Lecture for 1925 will be delivered by Sir Arthur J Evans in November next.

Lieut.-General Sir William B. Leishman, Director-General, Army Medical Service, Hon. Physician to the King; Sir Richard Lodge, professor of history, University of Edinburgh; and Mr William Rothenstein, Principal of the Royal College of Art, South Kensington, have been elected members of the Athenæum under the provisions of Rule II of the Club, which empowers the annual election by the Committee of a certain number of persons of distinguished eminence in science, literature, the arts, or for public service.

The spring conversazione of the staff of the Natural History Museum was held in the Board Room on March 4, and attracted the usual large attendance of members and visitors On this occasion most of the exhibits were selected to illustrate desert conditions and the effect of desiccation. They included fulgurites (lightning tubes), desert roses, and etched pebbles (the cause of the peculiar markings of which still remains an unsolved problem); Coleoptera, Diptera, and Lepidoptera, illustrating the development of desert colour; hares, rats, mongooses, and birds, showing the effect of desert environment; lizards illustrating modifications in the scales, eyes,

and feet, and desert plants showing the development of spines and prickly leaves as a protection against thirsty and hungry animals. Among the exhibits was a remarkable specimen of *Helix desotorum*, the common desert snail of Egypt, which was fixed on a tablet in the Museum in March 1846, and was found in March 1850 to be still alive after four years in a Museum case without food or moisture. The snail became torpid in October 1851, and was found to be dead in May 1852. Among the general exhibits may be mentioned specimens illustrating a recent study of the occurrence of Gongylonema in Italy by Dr L. W. Sambon and Dr H. A. Bayliss.

A JUNIOR scientific assistant is required by the Admiralty for research work. Candidates must possess an honours degree in physics or its equivalent, have a good knowledge of general physics, and have had some experience in research. Applications should be sent to the Secretary of the Admiralty (C.E.), Whitehall, S.W.1.

THE Experimental Department of H.M. Signal School, Portsmouth, invites application for a junior scientific assistantship from holders of an honours degree in physics or its equivalent. Applications should be sent, with particulars of qualifications and with testimonials, to the Secretary of the Admiralty (C.E.), Whitehall, S.W.1, not later than April 7.

WE have received from the Castner-Kellner Alkali Co., Ltd., a pamphlet on sodium peroxide. This compound was discovered by Gay Lussac and Thenard about 1810, but it was not until 1891 that it was manufactured on a large scale. The properties are described and the method of using the substance for bleaching purposes is set out in some detail. Useful tables of acid densities, etc., are also included in the booklet.

AN interesting tour in the Dordogne and Vézère Valleys during the Easter vacation (April 9-25) has been organised by Prof. Patrick Geddes. It will include visits to the principal prehistoric sites and caves in the neighbourhood of Les Eyziès under the guidance of Dr. Peyrony, the curator of the Musée Archéologique, who will also conduct the party around, and demonstrate, the collections in the museum. Dr. Peyrony has recently published an account of the investigations carried out by himself in company with L'Abbé Breuil and Dr. Capitan at Les Combarelles, and this opportunity of visiting the classical sites of palæolithic art and culture under his guidance should appeal to all who are interested in prehistoric archæology. The second part of the tour will be devoted to a series of excursions for the purpose of the study of the geography and history of the most attractive portions of the Dordogne Valley, Domme being taken as the centre. These excursions will be conducted by M. Paul Réclus. Particulars may be obtained from Miss M. M. Barker, 152 Abbey House, Victoria, S.W.1.

THE Women's Electrical Association has been formed with the immediate object of promoting the wider use of electricity in the service of women, and a large and representative council has been formed to guide its activities. Lectures and demonstrations of the applications of electricity are in hand, and the study of electrical applications in universities, colleges, and schools, particularly in relation to domestic subjects, is to be promoted. It is also proposed to institute a junior section which will be more especially concerned with girls' schools and colleges. Particulars can be obtained from the director of the Association, Miss C. Haslett, 26 George Street, Hanover Square, W.1.

WE have received a copy of the first issue of a new Italian monthly review entitled *Leonardo*, devoted to Italian culture in all its varied aspects, and published in Rome under the auspices of the Leonardo Trust and the editorship of Giuseppe Prezzolini. The review is illustrated, and is to be conducted apart from political influence and from the influence either of any literary or philosophical school, or of any firm of publishers. Its aims are not merely bibliographical, but comprise the study of cultural activities of all forms: scholastic, journalistic, theatrical, and even cinematographical. This first number contains, among other contributions, articles on the second International Book Fair, to be opened in Florence at the end of April, on the work of several Italian authors, and on British literature relating to Italian matters, together with a number of reviews of Italian books dealing with art, philosophy, hygiene, the literature of Italy and other countries, linguistics, medicine, pedagogy, geography, religion, social and political sciences, history, and the theatre. It is well produced, and should command a wide circulation, both in Italy and elsewhere.

THE Cambridge University Press announces for early publication vol. 1 of a new edition of "Principia Mathematica," by Prof. A. N. Whitehead and the Hon. Bertrand Russell. There will be three volumes in all.

AN interesting catalogue (No. 467) of some 1300 second-hand books on anthropology, folk-lore, archæology, and sociology has just been issued by Mr. F. Edwards, 83 High Street, Marylebone, W.1. Copies can be obtained upon application.

WE learn that Messrs. J. W. Atha and Co., who are the distributors for Messrs. Carl Zeiss, Jena, have now transferred their business to larger and better equipped premises at Winsley House, Wells Street, Oxford Street, London, W.1.

THE Schlomann-Oldenbourg Illustrated Technical Dictionaries in English, French, German, Italian, Russian, and Spanish, are familiar works. A British office has now been opened with Mr. H. I. Lewenz as editor and manager, and he will be responsible for the English terms and phrases contained in the dictionaries. Volumes are to be issued shortly on weaving and woven materials, on mining, agricultural machinery, chemistry, gas engineering, etc. The work is issued and stocked by Messrs. Lewenz and Wilkinson, Ltd., 25 Victoria Street, Westminster, S.W.1.

Research Items.

FURTHER EXCAVATIONS AT SOLUTRÉ.—*La Nature*, February 14, contains an illustrated report of the excavations at the prehistoric station of Crot-du-Charnier, Solutré, in 1924, which was presented to the Paris Academy of Sciences by MM. Depéret, Arcelin and Mayet on December 15 last. The trench in which three skeletons were found in 1923 was carried farther to the west and revealed the continuation of the thick, undisturbed bed of horse-bone magma. Immediately beneath this was found a fourth skeleton, a male, of Aurignacian age, as was revealed by the associated implements — gravers, flakes, scrapers, etc. Three stone slabs were placed on a level with the head. The legs of this skeleton had been destroyed by the excavations of the Abbé Ducrost in 1875. A fifth skeleton was that of a young woman which lay, not beneath, but actually in the horse-bone bed, which showed no sign of disturbance The skeleton had clearly been buried there during the period of formation of the bone-bed, which is nothing but the kitchen refuse heap of the Aurignacian hunters, who fed on the horse. This skeleton had no sepulchral slab A detailed description of the skeletons by Dr. Mayet is in course of preparation A preliminary report shows that the fourth skeleton is a male of about 40 years of age, in height 1·67 m to 1·70 m , dolichocephalic, but with a tendency to brachycephaly—index 77 89 The cranium is relatively high, the face broad but low, with prominent cheek bones, orbits quadrangular, low and elongated with an index of 69·7. The fifth skeleton is a female of about 30 years, in height the same as skeleton No. 1—1·53 m. to 1·55 m —cephalic index 83·24, face broad and very low, orbits oblique, oval and mesoseme—index 86·5. In general it shows a striking resemblance to the female skeleton No 1 found in 1923 The suggestion that the women belong to a different ethnic group is plausible, although it is recognised that in many ethnic groups the men are big and the women small.

BRONZE IN CHINA.—M A. Vayson de Pradenne, in collaboration with M G Chesneau, Director of the École Nationale Supérieure des Mines, has published in *L'Anthropologie*, T. 34, 6, a metallurgical and archæological study of bronze weapons from China, with special reference to two swords and a halberd which are tentatively assigned to the end of the Bronze Age The interest of the three weapons in question lies in the fact that not only are they in an excellent state of preservation, but also that they had been tinned The tinning had taken place after the smoothing and polishing process which followed the casting An analysis of the bronze shows: tin 16 44, copper 82·32, lead 0·15, iron 0·43, zinc 0·20, and of manganese, nickel, and arsenic, traces only. The superficial area shows tin only, with traces of copper at the point of contact with the bronze. The bronze is therefore of a composition which gives the maximum hardness without being brittle, the limit for a weapon which was to receive blows without risk of fracture being put at 16·17 per cent. of tin. It is suggested that the tinning was a device to obtain greater hardness without increasing the brittleness of the weapon The superposition of tin on the bronze has produced a thin hard layer which offers greater resistance than the inner metal to a steel drill. It is clear that the weapons have been ground and polished after tinning so that the layer of harder metal forms the cutting edge.

CLIMATE AND PLANT DISTRIBUTION IN THE LIGHT OF THE FOSSIL RECORD.—In the Masters Lectures published in the Journal of the Royal Horticultural Society, vol. 50, part i., January 1925, Prof. A. C. Seward gives a delightful account of Arctic vegetation as studied by him in his Greenland visit of 1921. The keynote of his lectures is to be found in a vivid passage in the first paragraph, in which he speaks of the experience of collecting a fossil frond of a Gleichenia, similar to the living frond he had seen in a Malayan forest, from the rocks below a flower-sprinkled Greenland heath. Prof. Seward attempts to answer the question whether the fossil record of these Arctic latitudes, as symbolised by this Gleichenia, necessitates the assumption that in preglacial times tropical climatic conditions prevailed in these northern climes He points out that the wide range of climate and altitude covered to-day by Gleichenia suggests the need for caution in drawing such a conclusion. His analysis of the modern Arctic flora, with its dominant herbaceous perennial type, certainly contrasts strongly with the arboreal character of many fossil remains from these latitudes, but Prof Seward makes it clear that modern investigation has not yet justified the assumption that structure has been directly and profoundly modified by Arctic conditions His cautious inference appears to be that the contrast of living and extinct floras of Arctic regions like Greenland justifies the assumption of considerable climatic change such as would accompany the changes in the distribution of land and water, of land elevation and water circulation, that might be expected in vast periods of time, but do not involve the assumption of changes in the position of the earth's axis of a nature that the astronomers are not ready to concede.

DYING-BACK OF ROSE SHOOTS.—In the Journal of the Royal Horticultural Society, vol. 50, part i., January 1925, W J Dowson describes very fully a disease met with on rambler roses in the Society's garden at Wisley The organism responsible for the dying-back of the rose shoots proved to be an ascomycete with small perithecia and was identified as *Gnomonia Rubi*, Rehm. After culture of the isolated organism, successful inoculation experiments were carried out, and no doubt remains that this organism was responsible for the disease. Other occasional records of this parasite, together with field observation, suggest that whilst the fungus may be widely distributed (on brambles and roses) it is relatively rare and seldom does much damage to roses, in this case probably entering the plants through buds previously killed by frost.

SOME INDIAN EARTHWORMS.—Dr. J. Stephenson (Records Ind. Mus., 26, pp. 317-365, 3 pls., 1924) gives an account of some Indian earthworms and describes two new genera of Ocnerodrilinæ. Only a single endemic species—*Gordiodrilus travancorensis*—of this family has until recently been known in India. Michaelsen described a second—*Curgia narayani*—in 1921, and now Stephenson describes two new genera, Malabaria and Aphanascus, which belong to this family. Malabaria is probably the immediate ancestor of Aphanascus, and the latter very possibly leads on to Curgia. The discovery of these worms strengthens the evidence of a faunistic relationship between India and E. Africa. The author refers to the interest of the occurrence of the two new genera in the same place (South Malabar) and surmises that the origin of the younger genus Aphanascus has taken place here and at no remote period, and yet the morphological differences between the two genera are not inconsiderable. It would appear that large morphological changes—sufficient to give rise to new

genera—" may come about in no great length of time, and that evolution may proceed, at times, with large strides and at a rapid pace." The paper forms an interesting addition to the author's analysis of the phylogeny of Indian Megascolecidæ.

THE MEDUSÆ OF THE MEDITERRANEAN AND ADJACENT SEAS.—In the reports on the Danish Oceanographical Expeditions, 1908-10, to the Mediterranean and adjacent seas (vol. 2, pp. 67, 1924) Dr. P. L. Kramp describes the collection of medusæ—Anthomedusæ 8 species, Leptomedusæ 6, Trachymedusæ 11, Narcomedusæ 4, and Scyphomedusæ 6, and gives figures of the species and maps showing the distribution of many of them. No new species was secured, but the collections have increased our knowledge of the range of distribution. Of the 27 species collected in the Mediterranean, only one was a new record for that sea, but several species hitherto known from but a few localities have been found to be widely distributed, and 3 species hitherto known only from the Mediterranean have been found to occur in Cadiz Bay. Of the 17 species found by the *Thor* in the Atlantic, between the south coast of Ireland and the north coast of Morocco, seven—chiefly deep-sea forms—do not enter the Mediterranean. Dr. Kramp discusses in some detail the connexion between the distribution of the species and the hydrographical conditions.

PHILIPPINE EARTHQUAKES.—The Rev. M. Saderra Masó, who has studied the Philippine earthquakes for so many years, gives a catalogue of 52 earthquakes of intensities 7 to 10 (Rossi-Forel scale) during the years 1901-22 (Weather Bureau, Manila Central Observatory, for September 1922). Of these, 31 were strong enough to damage buildings. Most of them originated under the neighbouring parts of the China Sea, the Celebes Sea, and the Pacific, those taking place beneath land or the inter-island seas being of slighter intensity. In all cases, the areas of destruction were those occupied by alluvial deposits. As a rule, only poorly-built houses were injured, with one curious exception. During an earthquake in 1907, a modern addition to the front of an old building was entirely demolished, while the original portion suffered no injury.

STRUCTURE OF A DENDROID GRAPTOLITE.—The structure and development of an early form of Dictyonema from the Upper Cambrian of Shropshire has been studied by O. M. B. Bulman (*Geol. Mag.*, 1925, p. 50). The work was facilitated by using a method for separating the fossil from the matrix in which it was embedded. It is found that this species of Dictyonema approaches the true graptolites more nearly than do the later forms of the genus, since it shows no true common canal and no spiral arrangement of the hydrothecæ, both of which characters are present in Silurian species. This suggests that the dendroid graptolites have been derived from the true graptolites. The hydrothecæ are of two kinds, the smaller (called bithecæ) are budded off from the sides of the larger, and it is suggested that they lodged polyps of the nature of dactylozoids. The hollow transverse bars (dissepiments) joining the stipes are formed as outgrowths from the bithecæ.

NEPHELINE-SYENITES IN RAJPUTANA.—In the Records of the Geological Survey of India (vol. 56, part 2, pp. 179-197, plates 2-12, 1924) Dr. A. M. Heron gives an account of the nepheline- and sodalite-bearing syenites of Kishengarh in Rajputana. These are of unusual interest on account of the occurrence, in some of their pegmatitic forms, of a peculiar sodalite which, when broken, is pale crimson on the freshly-opened surfaces, but rapidly turns to pale grey on exposure to bright daylight. The occurrence of this strange phenomenon was noticed first about twenty years ago (Rec. Geol. Surv. Ind., 31, 43, 1904; 32, 158, 1905), but its cause has never been worked out. During the visit of the British Association to Canada last year a similar peculiarity was noticed by members of a geological excursion party whilst examining the nepheline-syenite area in the Bancroft area, Ontario; and the change of colour, similarly from crimson to pale grey, is shown in this instance by white translucent sodalite. In the Kishengarh area the ordinary deep-blue sodalite occurs, as well as the variety which changes its colour. The felspathoid-bearing syenites of this area show considerable variations over a band some ten miles long and two miles broad. They occur mainly as sill-like intrusions among the Archæan schists, elongated in the direction of the general strike and often themselves both foliated and banded; but occasionally there are non-foliated pegmatitic forms with individual crystals of nepheline (elæolite) a foot or so in diameter. Among the accessory minerals of interest are thulite, cancrinite, and calcite, the last named being regarded as a primary constituent formed direct by consolidation of the magma, as in the case at Sivamalai, in South India, described by Holland in 1901 (Mem. Geol. Surv. Ind., 30, 169-217).

SWEDISH OCEANOGRAPHY.—Among the many valuable publications on Swedish meteorology and oceanography is the record made on certain lightships moored off the coasts of Sweden in the Gulf of Bothnia, the Baltic, and the Cattegat. The data from ten lightships for 1923 has now appeared (Svenska hydrografisk-biologiska kommissionens Fyrskepp-undersökning). In some cases the data for the year are incomplete, because ice necessitates the withdrawal of the lightship in winter and early spring. The first part of the volumes gives the noon records, including water temperatures at various depths and currents for the days each lightship was functioning. This is followed by salinity records, while the final part has a valuable series of water temperatures at different lightships at various depths in all months of the year for the years 1880 to 1913. This shows some remarkable variations in the Gulf of Bothnia and in the Sound.

BENTONITE.—The Canadian Department of Mines has recently issued an interesting paper on bentonite (Mines Branch, Pub. No. 626, by Hugh S. Spence, 1924), a peculiar clay-like material concerning which very little information has hitherto been available. Bentonite occurs in Wyoming and other western states of America, and appears to be widespread over the prairie provinces of Canada. It is found as a bedded sediment in thin deposits rarely so much as ten feet thick, most of which are of Upper Cretaceous age. Its most curious property is its tremendous swelling power when water is added. The volume at the maximum absorption may be five to thirteen times the dry bulk, and the mixture behaves like a true colloid. Nevertheless, the deposit is mainly composed of minute flakes of the definite mineral leverrierite, $2Al_2O_3 . 5SiO_2 . 5H_2O$. It also contains a noteworthy amount of adsorbed soda, and a further curious feature is that soda is frequently five times as abundant as potash. The origin of bentonite is traced to the hydration of thin water-laid beds of fine vitreous volcanic ash. The clay particles appear to have become dispersed as a suspension which afterwards coagulated and settled. The peculiar properties of bentonite should ultimately

give it an industrial importance, though at present there is only a small demand, largely on account of the high cost of transport. It has already been used as the base of many toilet creams and cosmetics; as a suspending agent in enamel mixtures, in the paper industry, and in the refining of oils and fats. The paper gives a long list of other possible applications, and a bibliography of the literature.

AMERICAN ASPHALT INDUSTRY.—Mr. K. W. Cottrell's report on "Asphalt and Related Bitumens in 1923" (Mineral Resources of the United States, part 2) indicates further progress in this industry, reflected especially in the marketing returns for that year. In the case of natural products the increase amounted to 22 per cent. in quantity and 28 per cent. in value over the previous year Manufactured asphalt from domestic petroleum, obtained chiefly from refineries in California, Texas, and Illinois, advanced 24 per cent in quantity and 26 per cent in value The total amount of asphalt produced from internal sources during 1923 amounted to 1,395,890 tons, corresponding to a market value of nearly sixteen million dollars To this must be added 1,378,722 tons manufactured from petroleum imported into the United States from Mexico, from which it may be observed that practically 50 per cent of the total output of asphalt in America is of Mexican origin Save for its utilisation in the paper-making industry (see NATURE, December 13, 1924, p 873) asphalt has apparently not found any new use during the year under review, the bulk still being employed for paving, roofing, and waterproofing purposes, though the rubber industry's demands have been heavier than in previous years The British Isles is still the largest consumer of asphalt and asphaltic products, Australia, Canada, France, Japan, Spain and Germany following in that order. The American asphalt industry now has its own Asphalt Association, a body composed of manufacturers, consumers and technical experts, whose purpose it is to disseminate practical information Co-operation of this kind, always a popular movement in the United States, is a sure sign of growing commercial activity in any industry, and in the present instance the trend of events is indicated by the fact that there are no less than forty independent groups operating in the country which are concerned with the production of asphalt and allied bituminous commodities.

THE MERCURY VAPOUR ENGINE.—One of the addresses delivered at the centenary of the Franklin Institute in September last dealt with the mercury vapour engine invented by Dr W. L. R. Emmet, of the General Electric Company, and it is printed in the February issue of the Journal of the Institute. The mercury is vaporised in a boiler at about 35 lb. per square inch pressure and passes to a mercury turbine coupled to a generator giving about 1800 kilowatts The waste heat of the vapour leaving the turbine is utilised in a tube steam boiler giving steam at about 200 lb. per sq. in. The condensed mercury runs back by gravitation to the mercury boiler. The furnace gases from the mercury boiler are used to heat the returning liquid mercury, then to superheat the steam raised in the steam boiler, and lastly to heat the feed water for that boiler. The plant has been run for several months at Hartford and has delivered power to the circuits for 800 hours without any troubles of a serious nature arising. A plant of 50,000 kilowatt capacity is to be installed at Chicago and a gain of output of 50 or 60 per cent. as compared with a modern steam turbine plant of that capacity is expected.

COLD-WORKING OF METALS AND HARDNESS.—The issue of *Die Naturwissenschaften* of January 2 contains an interesting article by Masing on the cold-working of metals and the resulting hardness produced, considered in the light of the modern work on single metallic crystals of Carpenter, Elam, and Taylor in Great Britain, and Polanyi, Mark, Schmidt, and Czochralski in Germany. The knowledge now gained is the result of a detailed study of the deformation of single crystal test pieces under stress which involves an experimental determination of the movement of the crystal axes during the test. The work of Taylor and Elam is especially noteworthy in this connexion. In their Bakerian Lecture two years ago they showed that in the distortion of a single crystal test piece of aluminium, the metal was deformed by movement on one octahedral plane up to an extension of 40 per cent. After this the crystal axes had moved in such a way that a second octahedral plane came into the conjugate position, and from there onwards the crystal elongated by being pulled out on two planes A point of special interest which emerged from their analysis was that the hardening of the crystal was general and not local, since, when the second plane came into position, the metal was equally resistant to distortion along this plane and that along which it had already been elongated In their recent paper to the Royal Society, Carpenter and Elam showed that the proportional increase in hardening is greatest during the early stages of extension, but that in the case of single crystals a stage is reached when the increase in hardness is approximately proportional to the amount of plastic deformation.

SULPHURIC ACID MANUFACTURE.—The *Chemical Age* for February 7 contains an interesting account of the new Gaillard method of intensive sulphuric acid production. Acid is sprayed on to the walls of an air-cooled lead tower from a "turbo-disperser" at the top. The impact breaks the drops, which then recoil and form in the body of the tower a heavy acid fog. Burner gases are passed up through this fog, which decomposes the nitrosyl sulphate, and condenses the acid already formed The process has been installed at San Carlos, near Malaga; the yields obtained correspond to a chamber space of 1 2 cu. ft. per pound of sulphur per 24 hours. The process works well with burner gases of both low and high sulphur dioxide content.

FLUCTUATIONS OF ASH AND NITROGEN IN LEAVES.—Jan Wlodek gives some interesting data as to the fluctuations in ash constituents and nitrogen in leaves collected at different hours of the day and night, in the Bulletin de l'Académie Polonaise des Sciences et des Lettres, Séries B, Sciences Naturelles, 1923, pp. 65-78. Many ash constituents show important fluctuations from night to day, these being best seen when the results of analysis are expressed as absolute values per biological unit, the leaf. In all three species investigated (*Phaseolus vulgaris*, *Trifolium pratense*, and *Avena sativa*) the sodium oxide content fell during the night, whilst potassium oxide fluctuated very strongly in Phaseolus, less in Trifolium. Magnesium oxide remained fairly constant; calcium oxide fluctuated irregularly; silica and SO_3 fell markedly during the night; chlorine remained about constant; P_2O_5 fluctuated irregularly. In oats the total nitrogen followed the silica content; in clover it varied irregularly. In oats the protein nitrogen on the other hand increased at night; in clover this also varied without regularity. These somewhat puzzling results are not discussed in the paper.

The Function of the Spleen.

THE number of functions attributed to any organ is often a direct measure of our ignorance as to its real status in the animal economy. The spleen has suffered much from a multiplicity of theories as to its functions, but only two appear to be generally accepted, in fœtal life it acts as one of the sources of the cells of the blood, whilst in the adult these cells, especially the red cells, are here broken down and destroyed when they become worn out. It appears from recent work by Prof. J. Barcroft and his collaborators, an account of which is given in the *Lancet* of February 14, that a further extremely important function must be attributed to this organ, in their opinion it acts as a storehouse for the red cells of the blood, a number of which may be kept there ready to be brought back into the circulation at a time of emergency.

These workers were first led to a study of this question by finding that when the blood volume increases on exposure of the body to a high external temperature, the increase is not entirely due to the addition of fluid alone to the circulating blood, but that at the same time the total hæmoglobin circulating in the blood increases also. There is no evidence of an increase in the number of newly formed red cells until after a few days have elapsed, so that the additional hæmoglobin—and corpuscles containing it—must have come from some store, and not be due to a new formation, at any rate at first; moreover, the rate of appearance of this hæmoglobin is too great for it to be due simply to new formation In their search for this store of red cells the investigators naturally thought of the spleen; if their supposition was to be considered correct, they must be able to answer in the affirmative these two questions: Is there, in fact, a store of red cells in the spleen, which are usually outside the general circulatory stream? Is the number of these stored cells sufficient to account for the increase in circulating hæmoglobin observed on exposure to a high external temperature?

The answer to the first question was found by an examination of the effects of breathing small amounts of carbon monoxide upon the blood in the spleen The experiments were conducted upon a number of different animals, and it was conclusively shown that there was a lag in the taking up of this gas by the red cells in the spleen as compared with those in the general circulation. In fact, if the percentage of gas breathed was sufficiently small, the hæmoglobin in the spleen might still contain none after several hours; on the other hand, when the animal was placed again in ordinary air, the carbon monoxide came off from the blood in the spleen much more slowly than from that in the general circulation. The blood in the spleen is thus outside the circulation, but this statement is only true for an animal at rest; in activity the carbon monoxide penetrates into the organ at once, so that under these conditions the stored blood appears to be in circulation. Further experiments have shown that under conditions where the amount of oxygen in the blood is less than normal, as, for example, after administration of carbon monoxide, the spleen is stimulated to contract by impulses from the central nervous system, the amount of blood forced out depending partly on the degree of such stimulation. Although it has been known for a long time that the spleen can undergo variations in size from the contraction of the unstriped muscle fibres it contains, the reason for this contractility is thus only now becoming apparent. Furthermore, bearing this capacity of the spleen to vary its size in mind, it may be asked: What is the real size of this organ? And are its variations in size of sufficient amplitude to account for the increase in circulating hæmoglobin with increase in the blood volume?

Little information on these questions can be derived from a study of the size of the spleen in the dead animal, since we have no means of knowing whether the muscle in it has maintained its *in vivo* length. We should expect to find, in fact, that it has contracted, so that the organ will be smaller than in life, but how much smaller we cannot judge It is clear that the organ must be examined in the living animal and without subjecting it to any exposure which might stimulate its smooth muscle fibres Since it is not opaque to the X-rays, Barcroft and his co-workers fastened small metal clips to its edges in the living animal under an anæsthetic After the wound had healed, X-ray photographs were taken in two planes, and from these it was easy to reconstruct in a model the size and shape of the organ under different conditions, the approximate weight was also ascertainable, after the animal had been killed, by comparing its size and weight after death with the size found during life It was found that the weight during life might be two to six times that observed after death, in fact, no less than one-sixth of the total blood volume, or one-third of the red cells, might be contained in the organ during life A comparison of its size at rest and during exercise suggests that an amount of blood equivalent to about one-quarter of the blood volume may be squeezed out of the organ during activity The evidence appears conclusive that a large amount of blood may be stored in the spleen, available for emergencies

Finally, since it is known that in man the spleen may be removed without apparent harm to the individual, Barcroft has inquired whether the absence or not of the organ makes any real difference to the organism. He found that animals without spleens died sooner than controls on exposure to an atmosphere containing carbon monoxide Thus an individual with a spleen will be able to meet an emergency with more success than one from whom the organ has been removed.

Science in Russia.

IT is gratifying to learn from a correspondent that, throughout the troubled period of the past few years, the splendid premises and wonderful collections of the famous Zoological Museum of the Academy of Sciences in Leningrad have scarcely felt the breath of war, famine, pestilence, and revolution which has passed over them. When the English traveller walks in, and is greeted by the famous young mammoth from Siberia, preserved like a recently killed specimen, and sees the rich collections illustrating the fauna of the vast steppes and deserts of Russian Asia, he feels that he is entering into a new world

During the cold winter of 1919–1920, when fuel was unobtainable, it was impossible to heat the Museum premises, but the staff suffered more than the collections Little or no looting was done during the disorders, except that the director had some difficulty in preventing the valuable collection of skins from being taken to be used as furs by the shivering population. Far more damage was done

during the severe floods last autumn, when the waters burst into the basement and ground floor, and at least one member of the staff actually saved his own life and that of others by swimming: the library was badly damaged, many valuable specimens were ruined by the water and damp, and great inconvenience was caused by the smashing of the stores of alcohol, which is difficult to obtain to-day in Russia, as the supply is under strict Government control and very limited

The entomological collections were enriched in 1914 by the generous gift by A P Semenov-Tian-Shansky of an immense collection of Central Asiatic Coleoptera, consisting of no less than 800,000 specimens the same donor last year presented his own collection of Hymenoptera, Diptera, Neuroptera.

The staff of the Zoological Museum consists of ten "senior zoologists," who form a "soviet" and elect their own director, ten "keepers," and eight assistants The present director is A A Bialitsky-Birula, well known from his work upon Arctic zoology, who is also editor of the *Annuaire* Birds are under the charge of P. P. Sushkin, Member of the Academy, who is well known in Great Britain and the United States. Another name well known outside his own country is that of the entomologist A. P. Semenov-Tian-Shansky, whose many friends will regret the sad news of his failing eyesight Fortunately, his general health leaves nothing to be desired, and it is to be hoped that he will be spared with capacity for useful work for many years. His father, P P Semenov, was a distinguished explorer, who surveyed the Tian Shan mountains, receiving the authority of the Tsar to add the title Tian-Shansky to his surname. Other well-known members of the staff are N J. Kuznetsov the lepidopterist, G G Jacobson the coleopterist, A K Mordvilko the aphidologist, P. I. Schmidt the ichthyologist, A N Kirichenko and A. M Diakonov, entomologists

The staff of the Museum are, of course, State officials, and paid at least a living wage: the salary of a senior zoologist is 47 gold roubles a month, equivalent to about 5*l* this, of course, leaves no margin for luxuries, but they are at least happy in their devotion to science Their chief complaint has been the shortage of modern foreign literature, but this is now to a certain extent being made good There is, however, considerable leeway to make up, and as the postal arrangements are now working satisfactorily, zoologists in England will be doing good work if they bear this in mind

During recent years it has not been possible to publish the results of research work in agriculture in Russia, since the scanty funds for agricultural publications have been used, in the first place, for publishing popular handbooks and pamphlets At the same time, research work has been carried on, often under most unfavourable conditions, and a considerable amount of new facts is awaiting publication The new journal (*Journal für landwirtschaftliche Wissenschaft*, vol 1 Nos 1-6, Moscow, 1924 (in Russian)), edited by a group of leading professors and research workers of the Moscow Agricultural Academy, aims at becoming a medium for publishing results of research work in all branches of agricultural science The five numbers (one double) before us now include a great variety of papers on different subjects

One of the most interesting papers is by A. G. Dojarenko, on the utilisation of solar energy by plants (No 1, pp 7-21), which describes the methods used in the author's experimental work for exact measurements of solar energy both received and utilised by cultivated plants, and gives interesting, though only preliminary, conclusions. Of considerable general interest is a paper by A. R. Minenkov (No. 1, pp. 29-47) dealing with the problem of chemical determination of sex in plants and in animals; the results of his experimental work are that both in plants and in animals there is a definite sexual difference in the fermenting properties of extract (plants) or blood (animals) which enables one to determine the sex A. D. Prianishnikov (No. 3, pp. 179-190) describes experiments on the transformation of nitrogen compounds in plants and in animals, the author's conclusion being that the analogies in this respect are very far-reaching and suggest a close similarity of processes in plants and in animals. In a paper by V Israilsky and E W. Runov the question of the action of vitamins on bacteria is discussed and experiments described, which tend to show that bacteria are very sensitive to vitamins. G. D. Karpetchenko (No. 5-6, pp 390-410) describes hybrids between two plants of different genera, *Raphanus sativus* L. and *Brassica oleracea* L.; an exhaustive study of the morphology and cytology of hybrids is given These are only a few of the more interesting papers from the journal, which represents, on the whole, an important step in the development of agricultural science in Russia The value of the journal to Russian agricultural research workers is greatly enhanced by abstracts of current literature.

University and Educational Intelligence.

BIRMINGHAM.—The Council of the University at its meeting on March 4 decided to go forward with its purpose for erecting further buildings at Edgbaston to accommodate the three biological departments, botany, zoology, and brewing, with the fermentation industries. The approximate estimate of expenditure is 90,000*l*-100,000*l*, and the scheme is only rendered possible by a very generous donation from Mr. W. Waters Butler of 35,000*l* Another donation to the fund of 5000*l*, given anonymously, was also reported. The Biological Departments are at present quite inadequately housed in Edmund Street, and the release of the space in the Edmund Street buildings will enable rearrangements to be made there to facilitate the work of the Faculties of Arts and Medicine, and the new Department of Law When the University was founded in 1900, an imposing scheme for the site at Edgbaston was planned by Sir Aston Webb Substantial progress had been made when the present buildings were opened by King Edward in 1909. The War and its economic consequences, however, prevented further progress. The new biological block is a resumption, long delayed, of the original plans.

CAMBRIDGE.—It is proposed to confer Honorary Degrees upon Prof. John Joly, professor of geology and mineralogy in the University of Dublin, and on Mr. A. P. Maudslay

The Board of Archæological and Anthropological Studies is recommending certain changes in the regulations for the diploma in anthropology. One change would throw open the diploma to any officer of one of the public services of the Empire, not ordinarily resident in the British Isles, who has resided and received instruction in anthropology in Cambridge during three terms or, in the case of an officer possessed of exceptional qualifications, during one term only.

LEEDS.—The degree of Doctor of Science has been awarded to Mr. H. Hunter for his thesis on "The Improvement of the Barley Crop"; and the degree

of Doctor of Medicine to Mr. C. G. K. Sharp for his thesis on "Bilharzia Disease." Dr. Sharp is the Chief Medical Inspector of Schools, Pietermaritzburg.

LONDON.—A course of three free public lectures on "The Cretaceous Vegetation of Greenland" will be delivered at University College on March 17, 20 and 24, at 5.30, by Prof. A. C. Seward. No tickets will be required.

MANCHESTER.—The Council has appointed Dr F. Craven Moore, lecturer in systematic medicine, to the chair of systematic medicine in the University. Dr. Craven Moore is the author of numerous papers, chiefly in connexion with diseases of the alimentary canal and metabolic medicine, among which may be mentioned "Cholesterin" and "Diseases of the Stomach" (Practical Encyclopedia, Medical Treatment, 1915), "Compensatory and Regenerative changes in the Liver," *British Medical Journal*, 1908; and "The Rôle of Fats in Treatment of Disorders of Stomach" (with Dr Ferguson), *Lancet*, 1909.

OXFORD.—The first annual report of the committee for the Lewis Evans collection of scientific instruments has just been issued by Mr. R. T Gunther, fellow of Magdalen College, the Curator The collection, which has now been appropriately housed in the Old Ashmolean Building, has received several important accessions in the course of the year. Interesting exhibits have also been deposited on loan by various colleges and by private collectors, and good progress has been made in the arrangement and labelling of the collection. That it has been possible to issue so favourable a report of progress in the proper display of this valuable collection is mainly due to the zeal and energy of Mr. Gunther The collection is to be officially opened on May 5, when the Earl of Crawford and Balcarres will deliver an address.

An examination for the Theodore Williams medical scholarship at Pembroke College, Oxford, will begin on June 9. The scholarship is of the annual value of 100*l*. and is tenable for either four or five years. Further particulars may be had from the senior tutor of the college.

DR. OTTO FISCHER, professor of chemistry at the University of Erlangen, who is retiring shortly, will be succeeded by Prof Rudolph Pummerer of Griefswald.

DR. ADOLPH HEILMANN, chief engineer of the municipal waterworks at Dresden, has been nominated to a professorship at the Technische Hochschule in Dresden.

DR. WALTER GOSSNER, professor of mineralogy at the University of Tübingen, has been invited to occupy the chair of mineralogy and crystallography at the University of Munich.

APPLICATIONS are invited for the chair of agriculture in Auckland University College, New Zealand. Particulars are to be had from the High Commissioner for New Zealand, 415 Strand, W.C.2. The completed forms must be returned by, at latest, March 31.

APPLICATIONS for not more than two Ramsay Memorial Fellowships for Chemical Research (one limited to candidates educated in Glasgow) are invited. The annual value of each fellowship is 250*l*., to which not more than 50*l*. for expenses may be added. The fellowships are normally tenable for two years with a possible extension for a further year. Applications must reach the Secretary of the Ramsay Memorial Fellowship Trust, University College, Gower Street, W.C.1, by June 6 at latest.

THE SCHOOLS RADIO SOCIETY, a section of the Radio Society of Great Britain, is arranging a Schools Radio Exhibition to be held at the L.C.C. Beaufoy Technical Institute, Princes Rd., Vauxhall Street, S.E., on March 14-18. Approximately 40 schools are exhibiting, consisting of members of the Schools Radio Society, L C C. Schools, and Technical Institutes. Apparatus made by scholars and sets used in schools will be shown together with schemes of school wireless work, and there will be a special display and demonstration by the British Broadcasting Company of what they consider to be the ideal set for broadcast reception Admission to the exhibition is by purchase of a programme or by invitation to be obtained from the Secretary, Schools Radio Society, St Paul's School, Dorking

AT the meeting of the Association of Technical Institutions on March 6 and 7, Mr G Mavor, head of the Department of Continuative Education at Loughborough College, in a paper on the conditions of training and education of apprentices, stated that the response to the appeal for information on the subject sent out to the leading firms in a great number of trades had been unsatisfactory as only about 10 per cent had replied From the replies received, it is, however, evident that while there may be a feeling in favour of apprenticeship, neither the trade unions nor the employers appear to be willing to enforce it. Where it exists, it is generally of the unindentured form, for 5 years, and not of an all-round type In some cases the local technical schools are asked to provide evening classes, but in the works the training is generally restricted to one branch, with the possibility of unemployment if the demands on that branch decrease To effect reform, Mr Mavor advocates the raising of the school leaving age to 16 and the provision of part daytime education for all employees up to the age of 18 Some firms have already adopted the latter, and others encourage their employees to attend evening classes, but State action is necessary if the requisite number of "warrant officers" for future industrial progress is to be produced

TEACHERS in technical and evening schools are being offered some very attractive short courses of instruction to be held next summer under arrangements made by the Board of Education at Birmingham, London, Oxford, Cambridge, and Harrogate The University of Birmingham is co-operating with the Board in the provision of courses in engineering science and electrical engineering at Birmingham and Oxford and in mining engineering at Birmingham. Prof. Burstall, Dean of the Faculty of Science, Profs. Batho, Cramp, Lea, Moss, J. S Haldane, MacGregor Morris, J. S Townsend, and other members of the University will deliver lectures and conduct demonstrations, tutorial classes, and discussions on teaching methods, and there are to be evening lectures by other eminent authorities in science and engineering The power house of the University as well as its departmental laboratories will be at the disposal of the instructors, and the University halls of residence will be used for the accommodation of those attending the courses At Oxford teachers attending the courses will be lodged in Oriel College At Cambridge a course in commercial subjects will be conducted at one of the colleges The courses in London will include building and surveying subjects and textile subjects The Board is to bear the cost of travelling to and from the places of instruction and to contribute a pound a week towards the cost of maintenance. Applications to attend must be sent to the Board before March 21.

Early Science at Oxford.

March 16, 1685–6. Dr. Garden of Aberdeen communicated his observations on the weather at Aberdeen in October, November and December 1685 Dr. Plot read a discourse concerning ye old Almanacks lately communicated by him, this will be printed in ye Doctor's History of Staffordshire

Mr. Thomas Wickam communicated the case of a Colt foaled with one of ye feet turned, ye heel standing forward, and ye toe backward, which being broken was set right, and grew together again so well, that ye Colt proved as serviceable a horse, as any of his condition thereabout

March 17, 1684–5.—With a letter from Mr Aston came ye Minutes of ye Dublin Society from December 1 to Feb. 23, 1684–5 inclusive Orders were given, that the thankes of our Society be returned for these Minutes, and that copies of Sir William Petty's *Supellex Philosophica*, and of Mr Brownlow's answers to ye Queries sent him concerning Lough-Neagh, be desired

A draught of Mr Beaumont's designe for writing ye History of ye Nature and Arts of the County of Somersett, was communicated

Dr Plot presented a Catalogue of some of ye most considerable Arcana and Desiderata in Chymistry as, followes —To reduce any of ye Metalls into a reall fluid To turne ye whole body of mercury into a clear Diaphanous water wetting ye hands To transmute one Metalline Species into another, especially ye baser, into gold and silver, either by projection, Cementation, Commixtion, or Digestion To make the liquor Alkahest, which will dissolve all bodies whatever, except its Compar, and what it is. To Sublime Antimony in it's own forme, black and striated To make a Menstruum, not corrosive, that shall perfectly dissolve all ye Metalls, particularly Gold and Silver To make urinous volatile Salt, or Spirit, from most Vegetables To make in good Quantity an Urinous Salt, and Spirit out of a Mineral with little cost To Mummiate an Animal entire without opening, or taking out the intestines, or giving to ye flesh any taste, colour, or smell To make glasse malleable To make many fragments of Diamonds, or other precious stones into one

March 18, 1683–4 —It was ordered that there be no election of Members into ye Philosophical Society, unless there be nine Members (at least) present, to make such election, which Article, with 13 others, agreed on March 11th, 1683–4, being entred in ye Journal Book, were subscribed, by Dr John Wallis, Savilian Professor of Geometry, Dr Ralph Bathurst, President of Trinity; Dr Beeston, Warden of New College, Dr Th Smith, Fellow of Magdalen; Dr Robert Plot, Professor of Chymistry, and Keeper of ye Musæum Ashmoleanum, Dr William Gibbons, St Johns, Edward Bernard, Savilian Professor of Astronomy, Jos Pulleyn of Magd Hall; John Caswell of Hart Hall, Th Piggot, of Wadham; S. Des-Masters, of Oriel; J Ballard and W. Musgrave, of New College, S Welsted, of Merton

We then passed to other Business Mr. Ballard informed ye Society, that ye Amianthus, on which his experiments were tried, was brought from Cyprus, by Dr Huntingdon, and communicated to us by Dr. Plot.

Manganese (a minerall, dug no where in England, but on Mendip-hills and used in ye purifying of glass) was not of itself affected by ye Magnet; but after above three hours calcination, it readily consented to it, as was shewn us by Dr. Plot. But Irish slate, calcined about four hours, could not be wrought on by ye Magnet; which gave Dr. Plot an occasion to draw up a discourse concerning severall Minerall waters, commonly thought to be Vitriol.

Societies and Academies.

LONDON.

Royal Society, March 5.—Sir Arthur **Schuster**: On the life statistics of fellows of the Royal Society. A revision and extension of a statistical inquiry made by Lieut.-Gen. R Strachey towards the end of last century Its principal results are: (1) The average age at election remained fairly constant between the years 1848, when the nominations for election were placed into the hands of the Council, and the end of the century, the average being 44·4 years There has been a decided increase since then, more especially in the last ten years, but some of this may have been due to war conditions. (2) The average age of fellows on January 1, 1923, was 60·9 years. (3) Their expectation of life is about 6 years greater than that recorded in the tables published in "Whitaker's Almanac" as applying to the entire population of England —G. I **Taylor** and Miss C. F **Elam** The plastic extension and fracture of aluminium crystals. In the early stages of the tests under direct tension the previous results are confirmed, and the nature of the distortion in the later stages is now proved to be due to slipping on the two crystal planes previously indicated After double slipping has begun, the rate of slip on the original slip-plane is usually greater than that on the new one The geometrical conditions with a shearing-stress parallel to the slip plane are such that the crystal is quite stable while the slip occurs on one plane, but as soon as double slipping occurs, it becomes far less stable, or even unstable. Therefore the specimen usually breaks before it has slipped far on the second plane, but never before the double slipping begins —A **Fage** An experimental study of the vibrations in the blades and shaft of an airscrew The sounds emitted were analysed with 4 Tucker hot-wire microphones used in conjunction with a four-valve amplifier. The sounds of rotation which arise from the rotation of the source-and-sink system associated with the pressure differences on the blades are composed of a large number of harmonics, having as fundamental a note of frequency equal to the product of the number of blades and the rotational speed The natural frequencies of flexural vibration were measured for four-blade shapes, the variables of design being width and geometrical pitch. The measured frequencies of the shaft vibrations agree very closely with the calculated results, except for a discrepancy of 8 per cent obtained on the heaviest airscrew —J. H **Vincent** and A L. **Beak**. Experiments on the effects of resistance in the oscillating circuit of a triode. The circuit employed is that previously used by Eccles and Vincent. In this the main oscillator consists of a condenser and coil in series, the coil being variably coupled to the grid coil which is in conductive connexion with a point between the condenser and main coil, the opposite point being joined to the negative end of the plate battery, these two points divide the main oscillating circuit into two branches, inductive and capacitive. With this apparatus the conditions were studied under which oscillations could be started and maintained, and the changes in frequency of oscillations and the simultaneous changes in the oscillating and mean plate currents, due to altering resistances in the inductive and capacitive branches of the oscillating circuit. The chief results support Eccles's control equation, but disagree with his formula for changes in frequency. G. H. **Hardy**. The lattice points of a circle. Proof of the fundamental identity in the problem of the circle by means of a singular integral the kernel of which is a theta-function, with an application to a theorem of J. E. Littlewood and A. Walfisz, published

recently in the Proceedings.—**H. M. Macdonald**: The transmission of electric waves around the earth's surface. The transmission of wireless signals to great distances and other phenomena associated with wireless telegraphy have been ascribed to the presence of a conducting layer in the upper atmosphere. Such a layer, if it were conducting in the ordinary sense, would act as a screen in respect of electrical effects having their origin external to the layer, and electrical disturbances set up in the space between the earth's surface and the conducting layer would subside very slowly. It appears natural, therefore, to assume that, if there is reflection from the upper atmosphere, there must also be radiation through it, to allow a steady state to be attained in a comparatively short time. The simplest hypothesis consistent with this is that the upper atmosphere differs from the lower atmosphere in respect of the constants involved in the propagation of electrical effects, namely, the specific inductive capacity and the magnetic permeability. On this hypothesis the condition that a steady state of electrical oscillation can be set up in the lower atmosphere in a comparatively short time is investigated. Taking an ideal case, the condition is that the ratio of specific inductive capacities is approximately equal to the ratio of magnetic permeabilities.—**R. M. Wilmotte**: On the field of force near the neutral point produced by two equal coaxial coils with special reference to the Campbell standard of mutual inductance. The accuracy of any apparatus depending on the mutual inductance between two coils and another coil situated at the neutral circle formed by the magnetic field of the first two coils depends largely on the variation of the magnetic force near the neutral circle. An expression in terms of the magnetic forces produced by a circular current is obtained for the variation of the mutual inductance due to a small displacement from the neutral circle of a single turn of wire acting as the secondary to two co-axial single-layer coils.—**W. R. Dean**: On the theory of elastic stability. After Hooke's Law has been extended, two methods are available. The three conditions for the equilibrium of an elementary volume may be written down, correctly to the second order, by considering the forces acting upon it, or the strain energy may be calculated to the third order, and the equations obtained by variation. With a cylindrical shell the energy method is shorter. The equations refer in the first instance to the displacements of any point of the shell. To reduce them to equations connecting the displacements of points of the middle surface only, the displacements of any point are expanded in series of the distance of this point from the middle surface, and the boundary conditions at the faces are used.—**R. A. Frazer**: On the motion of circular cylinders in a viscous fluid. The paper is restricted to two-dimensional flow, and deals primarily with the motion of circular cylinders in fluids of great viscosity, inertia terms being neglected. The flow due to a stationary cylinder immersed in a uniform infinite river is treated as the limiting case of flow between two concentric boundaries, the stream being uniform over the outer, and stationary over the inner. The essential elements for a solution are obtained with arbitrary velocity distributions specified over any two mutually external circular cylinders. The stream-function is completed for the case where the cylinders are in steady rotation. Another type of motion investigated is where two spinning cylinders are rotated as a "planetary" system about a particular "focus." The cases examined include "planetary" systems, problems of contact, and the combined rotation and translation of a cylinder in proximity to a wall.

Geological Society, January 21.—**Léon W. Collet**. The latest ideas on the formation of the Alpine range. In 1905 Prof. E. Argand determined in the Pennine Alps the existence of six great recumbent folds or nappes. On the base of Argand's results, Dr. R. Staub found in the north-eastern part of the Swiss Alps the same tectonic elements, covered by six higher nappes belonging more to the type of the "thrust-masses" of the North-Western Highlands of Scotland than to the type of the recumbent folds of the Pennine Alps. This new series of nappes has been named by Staub the Austrides, for they form the main part of the Austrian Alps. Prof. L. Kober's discovery of a window or horizontal cut, due to erosion, in the nappes of the Austrides, revealing deeper nappes belonging to the Pennine series, shows that the nappes of the Austrides have been thrust over the Pennine nappes in the Austrian Alps, just as in the north-eastern part of Switzerland. Co-ordination of the work by Austrian and Swiss geologists was accomplished at the end of last year by Dr. Staub. Wegener's ideas on the drifting of continental masses are employed to explain the movement of the hinterland towards the foreland of the geosyncline. Foreland and hinterland constitute the boundaries of the great Alpine geosyncline; together they recall the two jaws of a vice. Prof. Argand has shown that the nappes of the Austrides belong to the hinterland; that is, to Africa or Gondwanaland. Therefore the Austrides, with the Préalpes, represent a small part of Africa resting on Europe or Eurasia.

February 4.—**A. Heard**. The petrology of the district between Nevin and Clynnogfawr (Carnarvonshire). Drift obscures most of the valleys, and conceals the greater part of the areas underlain by unaltered shales. Most of the sedimentary rocks consist of dark purplish-grey shales of *Didymograptus-bifidusage*, together with their metamorphosed representatives. In the north-western part of the area unfossiliferous pale-grey shales containing numerous ashy and fine-grained gritty bands are present. A large proportion of the exposed rocks consists of an igneous complex of post-Lower Arenig—pre-Old Red Sandstone age. The intrusive rocks present many petrological variations, including numerous different types of granite and quartz-porphyries, granophyres, porphyries of intermediate composition, and basic rocks. The "banding" of the constituents of the coarser-grained intrusive masses is peculiar. Neither hybridism nor any apparent chilling is exhibited at the junction of adjacent "bands," and the uppermost band invariably consists of the most basic rock.

CAMBRIDGE.

Philosophical Society, February 2.—**L. F. Curtiss**: A preliminary note on a direct determination of the distribution of intensity in the natural β-ray spectrum of radium-B and radium-C. The number of electrons in each small range of velocity in the β-ray spectrum of radium-B and -C is measured by observing the charge communicated to a Faraday cylinder. The advantage is that full weight is given to every portion of the spectrum, and errors due to the variation of ionisation with velocity are avoided. Since in this method it was unnecessary to have any covering over the mouth of the Faraday cylinder, it was possible to investigate very low velocities, and an interesting emission was found about 250 $H\rho$.—**C. D. Ellis and W. A. Wooster**: Note on the heating effect of the γ-rays from radium-B and radium-C. The chief difficulty in this determination is due to the presence of the α-rays from radium-C; they produced a heating

one hundred times as great as that due to the γ-rays. This was overcome by an automatic compensation method. The rise in temperature was measured by means of thermocouples and the equivalent amount of heat found by calibration experiments with heating coils. The amount of radium-B + C in equilibrium with 1 gram of radium emits 8·1 cal./hour in the form of γ-rays.—C. D. **Ellis** and M. **Bowman-Manifold**: The interpretation of β-ray absorption curves. The approximate exponential absorption curves are due to the initial heterogeneity of the radiation. The absorption curve of a continuous spectrum can be explained by the superposition of the linear absorptions of the β-rays contained in each small range of velocities. The form of the continuous spectrum is simply related to the second differential coefficient of the absorption curve.—D. **Stockdale**: A thermostat for high temperatures. The instrument is designed to control the heating of electrical resistance furnaces. The electro-motive force given by a thermocouple, the hot junction of which is placed in the furnace, is balanced against the fall of potential along a wire. If the system is not in equilibrium, a galvanometer is deflected, and a boom carried by this galvanometer touches a wheel, an electrical circuit is closed and a relay is actuated in such a way that the current heating the furnace is altered until equilibrium is again established. It was fairly easy to maintain any temperature up to 1000° C. with a fluctuation of not more than 3° C.—W. G. **Palmer**. A method of finding the composition of adsorption films of mixed gases. The gas in an adsorption layer between two fine metallic filaments in mechanical contact can be removed, and metallic contact established by applying to the junction an electric stress, the value of which is characteristic of a particular gas and adsorbing material. When a bare surface first comes into contact with a mixture of gases, the composition of the initial film formed is directly calculable from the partial pressures and molecular weights of the gases. This film will in general change in composition to an equilibrium value. The composition of this final film is given by plotting the relation between electric stress required to remove the initial film and the composition of this film.—A. P. **Cary** and E. K. **Rideal**. The spreading of oils and fats on water surfaces.—W. **Saddler**. Triple binary forms; the complete system for a single (1, 1, 1) form with its geometrical interpretation.—W. **Burnside**: On the phrase "equally probable."

Dublin

Royal Dublin Society, January 27.—G. **Brownlee**: The interpretation of certain empirical standards in their application to Irish butter. An investigation of a large number of samples of butter, collected from various creameries by the inspectors of the Department of Agriculture and Technical Instruction of the Irish Free State, has shown that, during the months of November, December, and January, the Reichert-Wolny number of Irish butter is usually below the value 24, which is generally taken as the lower limit for pure butter. This is in agreement with the results of a previous investigation carried out some years ago. The values obtained for the other numbers used for defining the properties of butter also frequently fell outside the limits generally assumed to be applicable to pure butter.—E. A. **Werner**: The decomposition of certain amino acids by alkaline hypobromite.

Rome.

Royal Academy of the Lincei, November 2.—F. **Zambonini** and G. **Carobbi**: Double sulphates of rare earth and alkali metals. I. Double sulphates of lanthanum and potassium. Systematic study of the ternary systems composed of these two sulphates and water shows the existence of six compounds containing $La_2(SO_4)_3$, K_2SO_4 and H_2O in the molecular proportions, 1 : 5·2, 1 : 4·5 : 2, 1 : 4 : 1, 1 : 3 : 0, 2 . 3 8, and 1 : 1 : 2 respectively.—Ferruccio **Zambonini** and V. **Caglioti**: Double sulphates of rare earth and alkali metals. II. Double sulphates of neodymium and potassium. In this case the molecular proportions of the components of the double salts are 1 : 5 : 2, 1 : 4 : 2, 1 · 4 · 1, 1 3 : 2, 2 : 3 · 8, and 1 : 1 : 2.—V. **Ronchi**: An interferential method for the direct determination of the constants and aberrations of divergent optical systems. The method of combination fringes previously applied to convergent optical systems is simplified by the use of an auto-collimating arrangement as so to require only a single grating.—Dino **Bigiavi**: Action of nitrous acid on the azophenols. With nitrous acid, *p* : *p*′-dihydroxyazophenol yields a dinitroazophenol, and is also partly oxidised to *p*-nitrophenol, the diazo-group undergoing rupture, benzeneazo-α-naphthol also appears to suffer oxidation, whilst other azo-phenols yield diazonium salts, together with products not yet investigated.—G. **Carobbi**: Double nitrates of metals of the cerium group with copper and with cadmium. Compounds of the type $2X(NO_3)_3$, $3Ca(NO_3)_2$, $24H_2O$, where X represents Nd, Pr, Sm, and of the type $2X(NO_3)_3$, $3Cd(NO_3)_2$, $24H_2O$, where X represents La, Ce, Nd, are described, by means of the double nitrates formed with copper, lanthanum may be separated from præseodymium.—Gustavo **Cumin**: Geological data on the Istrian mountain region. II. Tectonics and morphology.—Marcello **Boldrini**: Internal and external measurements of certain long bones in man and in woman. II. Measurement of the intensity of the secondary sexual characters.—Cesare **Artom**: Numerical disproportion of the sexes in *Gambusia holbrooki* (Grd.) analysed as to its manifold causes. For most generations of the top-minnow, the numerical relation of the sexes at birth is 1 . 1, but in one autumnal generation a predominance of females was observed.—Boldrino **Boldrini**: Biological reactions observed in the blood serum of woman during and after the lacteal decline. II. Demonstration of an agglutinin of the globules of human milk.—Primo **Dorello**: Contribution to the knowledge of the biology of the nemasperms in the pulmonated gasteropods.—Carlo **Jucci**: Bivoltinism and parthenogenesis in silkworms (*Bombyx mori*).—Sergio **Sergi**: Myorabdotic cellular groups in the cervical region of the spinal medulla of the chimpanzee.

November 16, 1924.—Luigi **Bianchi**. A class of pairs of stratifiable rectilinear congruences.—G. **Bruni** and G. R. **Levi**: Solid solutions between compounds of elements of different valencies. The formation of solid solutions of lithium and magnesium fluorides, previously indicated by the results of thermal analysis of the system, is confirmed by X-ray examination. The substitution of magnesium fluoride molecules for a corresponding number of double lithium fluoride molecules produces neither an appreciable alteration in the lithium fluoride lattice nor the appearance of new lines in the photograms.—F. **Zambonini** and V. **Caglioti**: Double sulphates of the rare earth and alkali metals. II. Neodymium and potassium sulphates. Descriptions are given of the various double sulphates previously found.—Federico **Sacco**: An opened nummulite.—J. **Pérès**: Transformations which maintain the composition.—Bruto **Caldonazzo**: Differential geometry of surfaces of hydrodynamic interest.—Umberto

Crudeli: Rhombic systems with uniform rotation in electronic dynamics.—Paolo **Stranco**: Theory of Einstein fields with axial symmetry.—Guido Horn **d'Arturo**: Flying shadows visible during solar eclipses.—Rita **Brunetti**: Fine structure of the helium line 5876 Å.U.—G. **Carobbi**: Double chromates of rare earth and alkali metals I. Lanthanum and potassium chromates. Investigation of the isotherm for 25° reveals the existence of double salts containing $La(CrO_4)_3$, K_2CrO_4, and H_2O in the molecular proportions, 1 : 1 : 2, 1 3 : 2, 1 : 4 : 2, 1 . 4·5 · 2, and 1 : 5 . 2, these corresponding with the proportions found in the double sulphates of the same metals, excepting that, in the latter case, the 1 . 3-compound is anhydrous, and the 1 · 4-salt monohydrated.—Roberto **Savelli**: Genetic value of the process of fonolysis of gametes.—Marcello **Boldrini**: Internal and external measurements of certain long bones in man and in woman III The volume of the medullary cavity and hematopoiesis in the two sexes.—A **Clementi**: Adaptation of tadpoles to the chemico-physical conditions of the surrounding medium.—Boldrino **Boldrini** Biological reactions observed in the blood serum of woman during and after the lacteal decline. III. Demonstration of the existence of proteolytic enzymes capable of hydrolysing the proteins of human milk.—Carlo **Jucci**: Varying prochivity to parthenogenesis in different races of silkworms (*Bombyx mori*) and its probable correlation with the varying tendency to bivoltinism.—Sergio **Sergi**: Myorabdotic cellular groups in the thoracic region and the limits between the thoracic and lumbar regions in the spinal medulla of the chimpanzee

VIENNA.

Academy of Sciences, January 8.—K **Umrath** The conduction of excitation in the leaf of *Mimosa pudica*. The velocity of conduction is discontinuous and is dependent on the nature and strength of the stimulus The separate stages may be ascribed to separate conducting systems The velocity is less in the leaflets than in the secondary leaf-stalk, and less in them than in the primary leaf-stalk The system of greatest velocity is in the chief bundles.—T. **Ciuropajlowicz**: Two proofs of Fermat's great theorem.—I. **Waldmann**: Report on the geological survey of Moravian territory between Eggenburg, Pernegg, and Theras A series of orthogneiss intrusions and strata of rocks of sedimentary origin.—G. **Weissenberger**, F **Schuster**, and K **Wojnoff**. Molecular compounds of the phenols VI. The behaviour of hydrated cresols and allied compounds.—L. **Moser** and E. **Reitschl**: The determination and separation of the rare metals from other metals. VI. Determination of the solubility and sensitiveness of complex compounds of cæsium and rubidium and their application in analysis For quantitative analysis only the chloroplatinate, perchlorate, and bitartrate come into consideration. A quantitative separation was not attained There is no special cæsium or rubidium reagent, only sensitiveness is decisive. The best indication is given by silico-molybdic acid, by which potassium is not precipitated. Phosphotungstic acid is still more sensitive, but precipitates potassium also

Official Publications Received.

University of London: University College. Report of the University College Committee (February 1924–February 1925), with Financial Statements (for the Session 1923-24), and other Documents, for Presentation to the Senate. Pp. 101. (London.)

Diary of Societies.

SATURDAY, MARCH 14.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: The Counting of the Atoms (III.)

INSTITUTE OF BRITISH FOUNDRYMEN (Lancashire Branch) (at Manchester College of Technology), at 4.—G. Edgington. Oil-Sand Cores

SUNDAY, MARCH 15.

C.B.C. SOCIETY FOR CONSTRUCTIVE BIRTH CONTROL AND RACIAL PROGRESS (at Criterion Theatre, Piccadilly Circus, W.), at 3.—Dr. H. M. Telling, Dr. M. Thomson, Dr. Jane L. Hawthorne, Dr. Marie Stopes, and others: Why Doctors Disagree about Birth Control.

MONDAY, MARCH 16.

ROYAL IRISH ACADEMY, at 4.15.

ROYAL GEOGRAPHICAL SOCIETY (at Lowther Lodge, Kensington Gore), at 5.—R. D. Oldham: The Portolan Maps of the Rhône Delta.

INSTITUTION OF AUTOMOBILE ENGINEERS (Loughborough Graduates' Meeting) (at Loughborough College), at 7.—E. R. Caffyn: A Few Features of Early Car Design.

INSTITUTION OF ELECTRICAL ENGINEERS (Mersey and North Wales (Liverpool) Centre) (at Liverpool University), at 7.—Informal Discussion on The Application of Electricity on Board Ship.

JUNIOR INSTITUTION OF ENGINEERS (North-Western Section) (at 16 St. Mary's Parsonage, Manchester), at 7.15.—J. A. Oliver: Industrial Electric Vehicles.

INSTITUTION OF AUTOMOBILE ENGINEERS (Scottish Centre) (at Royal Technical College, Glasgow), at 7.30.—F. G. Woollard: Some Notes on British Methods of Continuous Production.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—F. R. Hiorns: The Corporate Spirit in Architecture.

ARISTOTELIAN SOCIETY (at University of London Club), at 8.—H. G. Collingwood: The Nature and Aims of a Philosophy of History.

MEDICAL SOCIETY OF LONDON, at 8.—*Sir Bernard Spilsbury*: Wounds and other Injuries (Lettsomian Lectures) (III.).

ROYAL SOCIETY OF MEDICINE (Social Evening), at 9.30.—Dr. H. C. Cameron: John Locke, the Philosopher (1690), on the Upbringing of Children.

CHEMICAL INDUSTRY CLUB (at 2 Whitehall Court, S.W.).

TUESDAY, MARCH 17.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. J. A. Ryle: The Study of Gastric Function in Health and Disease (Goulstonian Lectures) (I.).

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.15.—Prof. E. N. da C. Andrade: The Evolution of the Scientific Instrument (II.).

ROYAL STATISTICAL SOCIETY (Royal Society of Arts), at 5.15.—C. W. Hurcomb: Official Railway Statistics in Great Britain.

MINERALOGICAL SOCIETY OF LONDON (at Geological Society), at 5.30.—S. Tomkeieff: The Structure of Aragonite.—E. D. Mountain: Potash-oligoclase from Mt. Erebus, South Victoria Land, and Anorthoclase from Mt. Kenya, E. Africa.—Dr. A. Brammall: Further Notes on the Association of Lime with other Oxides of RO-type in Minerals.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—Secretary: Report on the Additions made to the Society's Menagerie during the month of February 1925.—Rev. F. C. R. Jourdain: A Study on Parasitism in the Cuckoo.—C. R. Narayana Rao and B. S. Ramanna: A New Genus of the Family Eugystomatidæ (Batrachia).—Dr. Nellie B. Eales: External Characters, Skin, and Temporal Gland of a Fœtal African Elephant.—F. F. Laidlaw: Description of a New Genus and Two New Species of Dragon flies (Odonata) belonging to the Family Comphidæ from Tropical Asia.—Rev. Dr. F. J. Wyeth: The Development and Neuromery of the Mid-Brain and Hind-Brain in *Sphenodon punctatus*.

INSTITUTE OF MARINE ENGINEERS, at 6.30.—A. C. Hardy: Motor Passenger Vessels.

INSTITUTION OF ELECTRICAL ENGINEERS (North Midland Students' Section) (at Leeds University), at 7.—W. R. T. Skinner and G. E. Barrett: High-pressure and High-temperature Steam.

INSTITUTION OF ELECTRICAL ENGINEERS (North-Western Centre) (at Engineers' Club, Manchester), at 7.—Col. T. F. Purves: The Post Office and Automatic Telephones.

SOCIETY OF CHEMICAL INDUSTRY (Birmingham and Midland Section) (at Birmingham University), at 7.15.—H. T. Tizard: Address.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.30.—(Annual Meeting of Scientific and Technical Group.)—Dr. T. Slater Price: Some Modern Views on the Sensitivity of Emulsions.

HULL CHEMICAL ENGINEERING SOCIETY (at Grey Street, Hull), at 7.45.—N. Simkin: Some Aspects of Low-Temperature Carbonisation.

ROYAL SOCIETY OF MEDICINE (Pathology Section), at 8.30.—Annual Meeting.

INSTITUTION OF AUTOMOBILE ENGINEERS (Wolverhampton Centre) (at Wolverhampton).

SOCIETY OF DYERS AND COLOURISTS (Leeds Junior Branch) (Annual Meeting) (at Leeds).—Prof. A. G. Perkin: Paper.

WEDNESDAY, MARCH 18.

SOCIETY OF CHEMICAL INDUSTRY (Glasgow Section) (jointly with the Chemical Engineering Group) (at 39 Elmbank Crescent, Glasgow), at 7.—Prof. J. W. Hinchley: Address.

INSTITUTION OF ELECTRICAL ENGINEERS (Sheffield Sub-Centre) (at Sheffield University), at 7.30.—G. F. Jones: Some Considerations in the Design, Manufacture, and Testing of Broadcasting Wireless Receiving Apparatus.

INSTITUTE OF METALS (North-East Section) (at Armstrong College, Newcastle-upon-Tyne), at 7.30.—A. G. Lobley: Electric Furnaces.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—Sir Napier Shaw and H. Fahmy: The Energy of Saturated Air in a Natural Environment.—C. K. M. Douglas: The Relation between the Source of the Air and the Upper Air Temperature up to the Base of the Stratosphere.—A. H. R. Goldie: Waves at an approximately Horizontal Surface of Discontinuity in the Atmosphere.

ROYAL SOCIETY OF ARTS, at 8.—C. N. Friese-Greene: Colour Cinematography.

ENTOMOLOGICAL SOCIETY OF LONDON, at 8.

INSTITUTION OF AUTOMOBILE ENGINEERS (Birmingham Graduates' Meeting) (at Chamber of Commerce, Birmingham).

SOCIETY OF GLASS TECHNOLOGY (at Newcastle-upon-Tyne).

THURSDAY, MARCH 19.

ROYAL SOCIETY, at 4.30.—Sir William Hardy and Miss Ida Bircumshaw: Boundary Lubrication. Plane Surfaces and the Limitations of Amontons' Law (Bakerian Lecture).

LINNEAN SOCIETY OF LONDON, at 5.—A. S. Hirst: Parasitic Mites found on Lizards.—W. R. B. Oliver: Biogeographical Relations of the New Zealand Region.—Mrs. M. Roach: A Study of the Physiology of certain Soil-Algæ in Pure Culture.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. A. J. Ryle: The Study of Gastric Function in Health and Disease (Goulstonian Lectures) (II.).

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.15.—Dr. Leonard Hill: The Biological Action of Light (II.).

ROYAL AERONAUTICAL SOCIETY, at 5.30.—Capt. F. Tymms: Practical Navigation of Aircraft.

INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5.30.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Councillor B. T. Cooke: What the Miners' Welfare Fund is doing for Children and Young People in Mining Communities.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—Presentation of the Faraday Medal to Sir J. J. Thomson.—S. Evershed: Permanent Magnets in Theory and Practice.

INSTITUTION OF AUTOMOBILE ENGINEERS (Graduates' Meeting) (at Watergate House, Adelphi), at 7.30.

INSTITUTE OF CHEMISTRY (Bristol Section) (at Bristol University), at 7.30.—Annual Meeting.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (at Bolbec Hall, Newcastle-upon-Tyne), at 7.30.—B. J. Ives: Seaworthiness.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Middlesbrough Graduates' Section) (at Cleveland Scientific and Technical Institution, Middlesbrough), at 7.30.—E. A. Harroway: British and Foreign Shipyard Practice.

CHEMICAL SOCIETY, at 8.—D. H. Bangham and J. Stafford: The "Activation" of Graphite as a Sorbent of Oxygen.

INSTITUTE OF CHEMISTRY (Edinburgh and East of Scotland Section, jointly with the Society of Chemical Industry (Edinburgh and East of Scotland Section)) (at North British Station Hotel, Edinburgh), at 8.—Informal Meeting.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (Laboratory Meeting) (at Royal Army Medical College, Grosvenor Road, S.W.), at 8.15.—Demonstrations by Drs. D. Adams, A. W. Grace, E. Hindle and J. T. Duncan, H. B. Newham, A. S. Burgess, Col. M. Perry, Drs. H. Seidelin, A. C. Stevenson, J. Gordon Thomson, C. M. Wenyon, and Mr. A. L. Sheather, and Prof. Warrington Yorke.

SOCIETY OF DYERS AND COLOURISTS (West Riding Section).—H. P. Hird: Further Researches on Coal Combustion.

IPSWICH AND DISTRICT NATURAL HISTORY SOCIETY (at Ipswich).—F. J. Chittenden: Experiments with Fruit Trees.

FRIDAY, MARCH 20.

EUGENICS EDUCATION SOCIETY (at Royal Society), at 5.—Dr. J. Brownlee: The Present Tendencies of Population in Great Britain in respect of Quantity and Quality.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Demonstration of Specimens illustrating the Surgical Anatomy of the Middle Ear.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (Pictorial Group), at 7.—F. C. Tilney: Address.

SOCIETY OF CHEMICAL INDUSTRY (South Wales Section) (Annual General Meeting) (at Technical College, Cardiff), at 7.30.—G. H. Clegg: Chairman's Address.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—S. H. Hole: Modern Transport.

INSTITUTE OF METALS (London Local Section) (at Institute of Marine Engineers), at 7.30.—Open Discussion.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. J. W. McBain: Soaps and the Theory of Colloids.

SOCIETY OF DYERS AND COLOURISTS (Manchester Section) (at Manchester).—Dr. F. M. Rowe, A. C. Burns, and J. S. H. Davies: A New Reaction with certain Diazo Sulphonates derived from β-naphthol-1-Sulphonic Acid.

SATURDAY, MARCH 21.

BRITISH PSYCHOLOGICAL SOCIETY (at Bedford College, Regent's Park), at 3.—R. H. Thouless: The Physics of the Psychogalvanic Reflex Phenomenon.—Rev. R. C. McCarthy: The "Determining Tendency" and Conation.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: The Counting of the Atoms (IV.).

INSTITUTE OF BRITISH FOUNDRYMEN (Lancashire Branch: Junior Section) (at Manchester College of Technology), at 7.—H. Stead: Plate Moulding and the Patternmaker.

IPSWICH AND DISTRICT NATURAL HISTORY SOCIETY.—Dr. H. M. Cade: The Germ Theory of Disease (Pathogenic Bacteria).

PHYSIOLOGICAL SOCIETY (Annual General Meeting) (at University College).

PUBLIC LECTURES.

SATURDAY, MARCH 14.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Dr. R. L. Sherlock: Man as a Geological Agent.

TUESDAY, MARCH 17.

UNIVERSITY COLLEGE, at 5.30.—C. D. Forde: The Megalithic Monuments of Brittany.—Prof. A. C. Seward: The Cretaceous Vegetation of Greenland. (Succeeding Lectures on March 20, 24.)

CASTLE MUSEUM, NORWICH, at 8.—Prof. Adshead: Housing after Slum Clearance (Chadwick Lecture).

UNIVERSITY, LEEDS, at 8.—E. Percival: The Freshwater Zoology of Yorkshire.

WEDNESDAY, MARCH 18.

KING'S COLLEGE, at 5.30.—Prof. J. D. Wilson: Education and Industrial Democracy.

FRIDAY, MARCH 20.

UNIVERSITY COLLEGE, CARDIFF, at 7.—Dr. W. M. Feldman: Ante-Natal Child Physiology and Hygiene (Chadwick Lecture).

SATURDAY, MARCH 21.

UNIVERSITY COLLEGE, at 3.—Dr. F. M. Feldman: Post-Natal Child Physiology and Hygiene (Chadwick Lecture).

HORNIMAN MUSEUM (Forest Hill), at 3.30.—S. Hazzledine Warren: Who were the First Men?

SATURDAY, MARCH 21, 1925.

The Fate of the Energy of the Universe: a Tangled Skein.

THE two outstanding conceptions of the nineteenth century were undoubtedly the principle of the conservation of energy, and the closely allied and supplementary principle of the dissipation of energy. Energy was conserved amid all its protean changes, but at each change its availability was lessened. On these two foundations rests the whole structure of thermodynamics. Neither of these conceptions stands exactly where it did, though a good deal of strong evidence will be required to shake the former. In a remarkable paper, read before the Cambridge Philosophical Society only a few months before his death, Prof. Liveing, at the age of ninety-five, threw out a challenge to the latter. Looking back over an active career covering in point of time almost the whole of what we now call science, the veteran felt that the dissipation of energy was not the whole truth. This universe could not be destined to subside into a tideless sea of unavailable energy, moved by no currents, stirred by no ripple, changeless and unchangeable. Somewhere, by some unknown process, the degraded energy must be undergoing a process of renewal and reintegration, to play its part once more in the physical world.

It is interesting to find from the report of a recent address given to the Radio Society by its distinguished president, Sir Oliver Lodge, that similar conclusions have been reached by still another scientific worker of long and ripe experience. In view of his more than youthful energy and freshness of outlook, it would be absurd to call Sir Oliver a veteran, but it cannot be denied that he has had a longer experience of scientific thought than most. His suggestions are always worthy of consideration, and, moreover, are always made in such concrete and positive form as to leave no doubt as to what they are.

Of the earlier parts of Sir Oliver's address it is not necessary to give any account. Towards the end of his discourse, however, after reviewing the principal facts of atomic structure, of photo-electricity, of thermionics, and of radio-telegraphy, he leaves the beaten track of accepted theory and experiment and launches forth on new and dangerous seas of thought. For Sir Oliver Lodge is not content with expressing a belief in the reintegration of energy; he also has a definite theory, or at least the beginnings of a theory, as to how this reintegration is accomplished.

Sir Oliver is at the present time the doughtiest of the champions of the ether, as against the mathematicians of the relativistic school, who, if they do not actually deny its existence, have at least no use for such a medium; and it may be that in times to come this

insistence that a basis for the universe must be sought in a physical medium rather than in a set of equations will be regarded as not the least of his contributions to physics. To him the electron and the proton are local modifications of this all-embracing fluid; knots, or, perhaps, bubbles in the ether, a conception already made familiar by Sir Joseph Larmor. Thus matter, which is built up of protons and electrons, is just a manifestation of local peculiarities in the ether. The protons and electrons attract each other. "A little friction will disturb and separate them," Sir Oliver reminds us, "but they will get together again as soon as they can. Whenever they approach each other, they radiate. The more violent the clash, the more vigorous the radiation. Do they ever actually inextricably clash, and annihilate each other? It is not known that they ever do, there seems to be something which keeps them apart Things on earth seem too staid and quiet to allow of an actual destructive clash, or anything like mutual extermination But the operation is conceivable, and as we now know that some of the stars have a temperature to be reckoned in millions of degrees, strange and violent things may be going on there."

"We can," continues Sir Oliver, "at least contemplate the process and ask what would happen if they did; the answer is clear enough The two opposite charges would vanish in a puff of radiation; all that would persist of them would be their energy; there is no destroying that. The energy would no longer be localised in specks of matter, it would now wholly and obviously belong to the ether" Sir Oliver thus accepts the transformation of matter into radiant energy, which has been postulated by Jeans and others to account for the intense radiation from the stars; and further suggests that the energy for this colossal output of radiation is supplied by the liberation of the potential energy stored up in the knots or strains in the ether which constitute electrical charges. "Dr. Jeans tells us that the sun loses 4,000,000 tons of matter every second. That is the rate at which it is radiating ether waves—converting matter into ether energy and radiating it away." It may be that Sir Oliver's theory from one point of view adds nothing to Einstein's postulate of the equivalence of matter and energy. It does, however, provide a conceivable picture of the method of transformation, and to the physicist who thinks in pictures rather than in formulæ, this is no small boon.

The crux of the address, however, lies in the succeeding paragraph. "What I want to ask is," says Sir Oliver, "is there any reciprocity about this process? Matter can turn into radiation. Can radiation turn into matter? I surmise that it can, but not under ordinary conditions. I guess that the waste radiation careering through space from all the innumerable suns and through innumerable millenniums must have some result. I imagine them to be generating matter in the far depths of space; which matter can then by gravitation fall together and reproduce or keep in maintenance the whole material cosmos. I see no ultimate dissipation of energy in the universe. I see energy passing from matter to ether and back again."

These singular speculations, which we have recorded so far as possible in the author's own words, open up interesting vistas. If, as Sir Oliver suggests, these knots possess the property of re-forming themselves when untied, they are indeed ethereal strains wafting to this tangled skein of which we form a part, the promise of an immortality not only in the future but also in the past. But, as Sir Oliver himself reminds us, speculation is comparatively useless unless it can be tested, and we are sure that he would not have published this unless he had glimpsed some way in which it might be put to the test of experiment. An address to a popular audience did not, perhaps, afford a suitable occasion for the fuller exposition of these matters, which we hope he will shortly give us. In the meantime we may be grateful to Sir Oliver Lodge for his challenge to lift our eyes to the wider horizons. It is good to be reminded, in this age of scientific progress, how little we really know.

Population and Evolution.

Malthus and his Work. By Dr. James Bonar. Second edition. Pp. viii+438. (London: G. Allen and Unwin, Ltd., 1924.) 12*s.* 6*d.* net.

"IN October 1838, that is, fifteen months after I had begun my systematic enquiry, I happened to read for amusement Malthus on Population, and being well prepared to appreciate the struggle for existence which everywhere goes on from long continued observation of the habits of animals and plants, it at once struck me that under these circumstances favourable variations would tend to be preserved, and unfavourable ones to be destroyed."

In these words, Darwin in the well-known autobiographical sketch acknowledged his debt to Malthus. It is also well known that Wallace made a similar acknowledgment. In a letter to Prof. Newton he referred to the matter as follows:

"The most interesting coincidence in the matter, I think, is, that I, as well as Darwin, was led to the theory itself through Malthus—in my case it was his elaborate account of the action of 'preventive checks' in keeping down the population of savage races to a tolerably fixed but scanty number. This had strongly impressed me, and it suddenly flashed upon me that all animals are necessarily thus kept down—'the struggle for existence'—while variations, of which I

was always thinking, must necessarily often be beneficial, and would cause those varieties to increase while the injurious variations diminished."

On another occasion, Wallace commented upon the fact that, whereas in his own case it was the recollection of his previous reading of Malthus, which came to him while puzzling over the problems of organic life during an attack of fever when on a visit to the East, Darwin chanced to read Malthus when he had for some time already had the problem of evolution in mind.

This difference is of no moment; the profoundly interesting fact is that both the authors of the famous papers read to the Linnean Society on July 1, 1858, afterwards acknowledged their debt to Malthus. It is also an example of the fame of Malthus's book that two specialists in quite another field should have read the book more than forty years after the publication of the first edition. We may guess, however, that they did not pick up the book wholly by chance. They probably had some previous idea as to its contents, and were led to study it because they suspected, even if only half consciously, that the theme had some reference to their own studies. This turned out to be very much the case. Malthus was not a biologist or a naturalist, though it is perhaps worth noting that his father was an amateur botanist and specifically disposed in his will of a box of plants given to him by Rousseau. By training a mathematician (he was ninth wrangler in 1788), Malthus was by taste interested in social problems. At Cambridge he was "remarked for talking of what actually exists in nature or may be put to real practical use" rather than for abstract speculations. When, therefore, after leaving Cambridge, friendly discussions took place between him and his father, who looked kindly upon Jacobinism, the views of Godwin and prospects of "perfectibility," it is not surprising that the younger man "threw little stones" into his father's garden. The son saw practical difficulties in the way of "improving society" and concentrated his attention upon the difficulties connected with population as among the most serious.

Malthus was thus led to put his views in the form of an essay, which was much expanded in later editions. In the opening chapter, stress is laid upon "the prolific nature of plants or animals," to which there is no bound "but what is made by the crowding and interfering with each other's means of subsistence." Malthus, however, was not interested in plants or animals other than man, and it is with the consequences of man's power of multiplication that he is concerned. This hint, nevertheless, was of the utmost value to Darwin. "A struggle for existence inevitably follows from the high rate at which all organic beings tend to increase," he says in the famous third chapter of the "Origin of Species." The very phrase "struggle for existence" was, it is interesting to note, used by Malthus himself. After some further amplification of the idea of the struggle for existence, Darwin goes on to say that "it is the doctrine of Malthus applied with manifold force to the whole animal and vegetable kingdoms."

The influence of Malthus upon Darwin and Wallace is not merely a matter of historical interest. It reminds us of the fact that many social problems are, at the bottom, biological problems. There is nowadays a strong revival of interest in the question of population, and we may distinguish between problems connected with the quantity and problems connected with the quality of population. Upon both of these problems biologists have much of value to contribute. Indeed, for the solution of many problems of pressing practical importance, further biological research is urgently required. We know little, for example, regarding the comparative fecundity of different races and regarding the influence of variations in the food supply upon the fecundity of members of the same race. There are hints that crowding has an important, though an obscure, influence upon the power of multiplication. Upon these and other important points bearing upon the quantity of population, we await progress in biological inquiry. The problems regarding the quality of population, which were formerly much neglected, are now receiving attention and biologists are "throwing little stones" into the gardens of our modern counterparts of the old believers in "perfectibility." They could, however, take far more effective aim if they were furnished with more extensive and accurate data such as further research alone can provide.

The widespread interest in population which Malthus aroused gradually died away. To those concerned with social economics it came to seem a remote problem, and biologists had not advanced the study of inheritance far enough to be able to contribute much that was of value. Interest has now revived; the War has made certain aspects of pressing importance, and we may be sure that this time the problem has come to stay. Thus a warm welcome is ensured to the new edition of Dr. Bonar's well-known book. First published in 1885, it has long ago taken its place as a standard work and will now draw a still larger circle of readers. As the author says, it is not a treatise on population, but an account of one writer on population, and, we may add, a very illuminating and sympathetic account. There is a certain resemblance between Malthus and Darwin both in character and achievement. They were both retiring in disposition, courteous in manner, and capable of inspiring deep affection. They both

attained sudden fame by the publication of a single book; they were greatly maligned and, while feeling the attacks made upon them, were recompensed by the knowledge that they had in general gained the assent of the eminent men of their day to their views. Lastly, they both sought to avoid controversy and devoted themselves to gathering fresh evidence, leaving their supporters and detractors to fight it out among themselves.

Dr. Bonar has somewhat expanded the bibliographical section of his book. Otherwise it remains as it was, with the addition of certain notes. It is a book with which all those who interest themselves in population problems, and among them are nowadays many biologists, will wish to make themselves acquainted. A. M C.-S.

Relativity and Cosmology.

(1) *Einstein's Theory of Relativity.* By Prof Max Born. Translated by Henry L Brose Pp. xi + 293. (London: Methuen and Co, Ltd., 1924.) 12*s.* net

(2) *Space and Time. an Experimental Physicist's Conception of these Ideas and of their Alteration.* By Prof. Carl Benedicks. Pp xiv + 98. (London: Methuen and Co, Ltd., 1924) 4*s.* net.

(3) *The Theory of Relativity.* By Dr. L. Silberstein. Second edition, enlarged. Pp. x + 563 (London: Macmillan and Co, Ltd., 1924) 25*s.* net.

IT is nearly twenty years since Einstein wrote his epoch-making paper on the electrodynamics of moving bodies, in which the fundamental principles of the theory of relativity were first clearly enunciated, and apparently the theory is now approaching the completion of the stage of formal development on one hand and of popular exposition on the other. Writers are beginning to turn their attention to work of a more critical character on the roots of the theory — its logical bases and fundamental concepts — and to the detailed investigation of its outlying branches, spreading far into distant regions — the quantum theory, cosmological theories, and so forth. The three books under review are typical of this process in some respects, and each is well worthy of the reader's attention.

(1) The first book, by Max Born, the successor of W. Voigt in the chair of mathematical physics at the University of Göttingen, and himself well known for researches in the theory of relativity, is considered by some to give the best popular exposition of Einstein's theory in the German language, and for this reason alone an English translation is very welcome. It arose out of a course of popular lectures on the subject delivered in the winter of 1919–1920 to an audience without any knowledge of the technique of either mathematics or physics, and, although naturally the treatment has been modified somewhat with a view to publication, the result is an eminently readable account of the subject. No doubt it will in its English guise prove very useful, not only to the general reader and to the popular lecturer, but also to the university student in his first or second year with only a slender equipment of mathematics and physics. The treatment in the main follows the historical order of development, but always with special reference to questions of absolute and relative motion and similar changes. The first twenty-five pages are devoted to a brief sketch of Newtonian mechanics and Newton's ideas of absolute space and time, the next fifty to the fundamental laws of optics, including optical effects in moving bodies, and about sixty more to the fundamental laws of electrodynamics up to and including the theories of Hertz and of Lorentz, and an account of the Michelson-Morley experiment. On this broad foundation the special theory of relativity is expounded in fifty pages, and the general theory in a further forty pages, both mainly on the lines laid down by Einstein. The translation is good, misprints are conspicuous by their absence, and the print and style of production excellent.

(2) In the second book, Carl Benedicks, the eminent Swedish metallographist, deals with the fundamental principles of space and time measurements from the point of view of the experimenter rather than the logician or mathematician. He prefers the traditional views as to the absolute character of space and time and their independence of one another, and considers the reasons put forward by Einstein and his school for changing them to be quite insufficient. Without in the least minimising the value of Einstein's explanations of such residual effects as the deflexion of light by the sun and the advance of the perihelion of Mercury's orbit, he does not consider them to be decisive tests of the theory. He directs attention to a remark of Poincaré's to the effect that "if one explanation of a phenomenon is found, there are also an infinite number of other ones to be found," and points out that other explanations of both effects have been given already—by Von Soldner a hundred and ten years before Einstein for the deflexion of light, and by G. Bertrand recently for the perihelion effect. He inclines to the opinion that an emission theory of light, on the lines of the ideas put forward by W. Ritz just before his decease, might be constructed in such a way as to meet these difficulties without necessitating complete changes in the traditional concepts of space and time; for example, on this view an electron is regarded as the "centre of an iterated explosion." Whatever one may think of the author's conclusions, one must admit that this

book of some hundred pages contains much that is interesting and suggestive, and raises several questions well worthy of the attention of relativists, such as the realisation of a true plane by the engineer's method of constructing three mutually fitting face-plates, the synchronisation of two distant clocks by the mechanical device of two wheels connected by an axle free from torsion, etc. It can be strongly recommended to any one interested in the logical bases of mechanics and physics.

(3) The third book, by L. Silberstein, is in many respects the most important of the three, at any rate for the relativist, but no doubt it presupposes a much more extensive mathematical and physical equipment than the other two; it is the second edition, and at the same time an extensive development of the book on the theory of relativity published by the same author in 1914, and reviewed in NATURE of December 10 of that year. That book is reprinted practically without change and forms the first ten chapters of the present work, so that nothing further need be said about this portion. The six added chapters with a number of miscellaneous notes at the end, amounting to about two hundred and sixty pages, or a little less than one-half of the whole, deal with the extensions made in the theory since 1914, mainly in connexion with the general theory of relativity and gravitation, with detailed reference to its cosmological applications. The old and new parts of the book together constitute what is perhaps the most complete text-book in the English language on the theory of relativity and gravitation in all its ramifications, certainly the fullest on its cosmological aspects. It is worthy of a place beside the standard treatises of Eddington and of Weyl, but not quite as mathematical as the former and perhaps wider in scope than the latter, and written from rather a different point of view than either, so that the three books are in a sense complementary to one another.

The author has evidently been at great pains to make the physical meaning of each step in his argument and of every mathematical result as clear as possible, even to a reader not possessed of the very considerable mathematical equipment needed for a thorough understanding of the general theory of relativity. To expect complete success in this respect would, however, be unreasonable, seeing that there are plenty of mathematical processes and results in the theory, about the geometrical and physical meaning of which even experts are not yet fully agreed. We ought to bear in mind what were the conditions respecting the geometrical interpretation of the axioms and concepts of Euclidian geometry before the times of Gauss, Bolyai, and Lobatschewsky, or the physical interpretation of the concepts and laws of Newtonian mechanics before the time of Mach, particularly in view of the great age of these branches of knowledge as compared with the twenty years of relativity.

Coming to details we note that the first of the new chapters, the eleventh of the whole book, gives a very readable account, without any formidable array of mathematical symbols, of the logical and historical development which led Einstein from the special to the general theory of relativity. The metrical tensor of the field is introduced, its geometrical and physical implications are considered summarily, and the world geodesics are defined and their physical interpretation is explained. The twelfth chapter is purely mathematical; in fifty pages a brief account of the tensor calculus is given, Levi-Cività's concept of parallelism is explained, and the Riemann-Christoffel tensor is introduced in much the usual way. Naturally, the limitations of space imposed by the plan of the book make this chapter difficult for any one not already acquainted with the subject; full references are given to the original authorities, but it might have made it easier for the beginner if reference had also been made to fuller text-books on this particular branch, like those of Galbrun and of Rothe.

The thirteenth chapter deals in some twenty pages with the physical interpretation of geodesics in detail, and is noteworthy in two respects. In the first place, it is shown that in the rest system of a freely moving particle the equations of motion of Einstein become identical with the Newtonian equations, not merely approximately, as is generally known, but rigorously. Secondly, the treatment of the light paths, or rays, is novel and is utilised to obtain the theory of the experiments reported to have been carried out by Michelson at the Yerkes Observatory with the object of testing Einstein's theory by an absolutely direct method. The fourteenth chapter, of fifty pages, treats of the gravitational field equations and the material energy tensor in much the same manner as in other books, attention being confined, however, to the centrosymmetrical solutions and to Einstein's approximate method. Within these self-imposed limits the author gives an exceptionally complete treatment, including, as he does, an account of de Sitter's geodesic precession and also of Grossmann's critique of the perihelion effect.

The fifteenth chapter deals with electromagnetism and gravitation by a little-known method due to Kottler and based upon Minkowski's exposition of the special theory. In about twenty-three pages the author works out the field of a gravitating electric particle, as it were from first principles, a method of treatment which possesses certain advantages from the student's point of view over the usual method based on the principle of least action. The last seven pages of this

chapter contain a very brief sketch of variational methods, of which the author does not appear to be particularly enamoured; but he gives full references to the original authorities with the exception of de Donder, whose "Gravifique Einsteinienne" is not so well known as it deserves. The five new chapters so far considered cover the ground usual in text-books on the general theory of relativity, but in some respects the treatment is novel and more complete than usual, as we have pointed out here and there. The chief peculiarity of the book, however, lies in the very complete account of the cosmological aspects of the general theory of relativity, which fills nearly one-third of the additional space, about eighty pages.

The author devotes the first thirty pages of the sixteenth and last chapter to a very detailed critical discussion of Einstein's cosmology, based on the assumption of a finite elliptic space filled with matter, uniformly distributed on the average. He explains very clearly how this cosmology leads unavoidably to the existence of singularities of the metrical field—antisuns—at places where there need be no concentration of matter at all, and is therefore untenable, a conclusion in which he agrees with other writers. The remaining thirty or more pages of this chapter are devoted to a detailed study of de Sitter's cosmology, to which the author is evidently favourably disposed. He discusses de Sitter's spectroscopic distance effect, as well as the more general combined Doppler effect, due both to distance and to radial motion of a celestial object—star, nebula, or cluster—in considerable detail, in the light of Slipher's table of radial velocities of spiral nebulæ and Shapley's tables of the radial velocities of globular clusters. Finally, there are fifteen pages of miscellaneous notes dealing mainly with questions relating to world-curvature and cosmology, but also with some recent experimental results regarding the solar spectrum shift, the deflexion of light by the sun, and spectrum shifts of distant celestial objects. Although most relativists would perhaps be loth to lay so much stress as the author does on observations relating to very distant celestial objects, on account of the very speculative character of some of the interpretations put upon them, yet it must be conceded that there is much to be said in favour of the author's view that these observations do lend substantial support, so far as they go, to de Sitter's cosmology, which treats space as finite, elliptic, and generally void of matter, except for the presence here and there of isolated singularities, such as the sun and the stars.

This brief survey sufficiently shows that we have before us a book of great interest, which deals with many of the problems arising in the general theory of relativity in a detailed, novel, and up-to-date manner. It may be objected that it is premature to devote so great a proportion of the whole book as one-sixth to so speculative a branch as cosmology, but there is good reason to be thankful to the author for giving us so full an account of this usually neglected portion of the theory. For this and many other reasons, Dr. Silberstein's book is one which no one interested in the theory of relativity can afford to ignore.

The Canadian Arctic.

(1) *With Stefansson in the Arctic.* By Harold Noice. Pp. 270 + 16 plates. (London, Calcutta and Sydney: G. G. Harrap and Co., Ltd., 1924.) 7*s* 6*d*. net.

(2) *The Arctic Forests.* By Michael H. Mason. Pp. xiii + 320 + 53 Plates. (London: Hodder and Stoughton, Ltd., 1924.) 20*s* net.

(1) THE facile pen of Mr. Vilhjalmur Stefansson has already made us familiar with the Canadian Arctic islands and his views on the friendliness of Nature in the polar regions, but we may say without prejudice to the leader of the expedition that one needed the opinions and feelings of a rank-and-file member of the party to drive home the theories of the enthusiast. Mr. Noice tells in a frank and pleasant way the events of many months of intimate companionship with his leader, and incidentally unfolds his gradual conversion to the beliefs of Stefansson in a way which carries more conviction than the calm and scientific statements of "The Friendly Arctic" could do. There are also many gaps in the earlier narrative which are filled up in this, and new sidelights are thrown on some aspects, as, for example, on the insubordination which so frequently marred the plans and diverted the purpose of the expedition.

To British readers, accustomed now to Antarctic ventures, which of recent years have held the field, the expedition presents many unique features. The various headquarters of the expedition were rarely more than 300 miles from the Canadian mainland and not much more from the settlement at Herschel Island. In consequence, there were frequent opportunities for refitting from visiting whalers, or of dashing across to find new men or ships, a convenience which proved of doubtful value. Although it enabled the leader to buy or charter no fewer than four ships at various times, it also meant taking with them several men whom he could have done better without. The method of employing Eskimo men and women, though not new, was very thoroughly carried out, several women being at an advanced headquarters within 300 miles of the farthest point reached.

The most unprecedented feature of the expedition was the reliance for food on what could be found on the

land and under the ice, and the proof positive that for many parts of the region visited there is no need for any one to die of starvation so long as he is able to hunt. The abundance of animal and vegetable life is little short of amazing, and the demonstration carried out over some five years, that white men can live and hunt in the Eskimo method, is perhaps the greatest service the expedition has rendered to polar exploration.

The claim made in some quarters that this has ended the days of expeditions going out fully equipped from civilisation cannot be said to be substantiated, or at all events must not be accepted without challenge. To one who has served on what Mr. Stefansson humorously calls a "groceries" expedition, where little thought and the minimum of time was given to the daily food problem, the chief and lasting impression of these two narratives is the amount of time which has to be given up to hunting and cooking, and, one may also add, the number of caribou or ovibos (musk ox) required to support a party of three or four men with dogs. That a man of the mental calibre of Mr. Stefansson should have to spend day after day hunting for the party may have proved the efficiency of the white man, but at the same time it must have robbed us of a vast amount of skilful scientific observations.

It is true that the loss of time spent in hunting was to some extent made up by the rapid methods of travel which the parties used, and their ability to travel in almost any weather. The mileage travelled by Noice himself and by others is astonishing, though, owing to unforeseen circumstances, a great deal of it was spent in mere message-taking from one party to another. While the loss of two experienced men on one of the journeys warns us that the friendliness of the Arctic is strictly a relative term, there is no doubt that Mr. Noice's book supports the earlier one in demonstrating that life in the Canadian Arctic islands can be pleasant and exploration a mere matter of time, provided that Eskimo, and white men trained to Eskimo methods, are taken.

(2) In Mr. Mason's book we have the same kind of tale, though in slightly more favoured latitudes. The rapid development of the Alaskan territories and the amenities of life there now are little known to us in the Old World, who are apt to look to the tales of hardship in the early days of the "Yukon" for our ideas on the subject. The book perhaps attempts too much, in that it ranges from anthropological classifications through true and thrilling stories of camp life to imaginative tales of death and disaster. Each section is well written, but cannot claim its full effect when side by side with the others, and indeed conveys the impression of a guide-book compilation, which it is not. But the author most certainly succeeds in his purpose of giving an "accurate general idea" of the country, and will doubtless convert many readers to his firm belief in its future. We too are ready to dream of first-class dining-cars running to the shores of the Arctic Ocean during the summer, since the mineral wealth of the country is able to pay for them, but we hesitate to follow so readily the author's claim that it is only a matter of time before cereals will be acclimatised so as to feed the growing population without dependence on outside sources.

F. DEBENHAM.

Applied Chemistry.

The Constituents of Coal Tar. By Dr. P. E. Spielmann. (Monographs on Industrial Chemistry.) Pp. xii + 219. (London: Longmans, Green and Co., 1924.) 12*s.* 6*d.* net.

Aniline and its Derivatives. By P. H. Groggins. Pp. vii + 256. (London: Chapman and Hall, Ltd., 1924.) 18*s.* net.

THESE two books present a sharp contrast which is of particular interest at the present time, when many people are concerned to notice in some of our educational institutions a tendency towards early specialisation and the consequent granting of degrees and diplomas to students who have not received, and have not had time to receive, a thorough training in the sciences underlying the branch of applied chemistry they have chosen to adopt. For, after all, applied chemistry is applied *chemistry*, that is to say, it is a branch of chemistry, not a science of itself, and a chemist is, or should be, a *chemist* before he elects to follow any of the numerous branches of the parent science which will enable him to adopt an adjectived or hyphenated title. It is scarcely possible to insist too strongly on this point because it is difficult adequately to acquire the fundamental principles of a science in later life, and the early neglect of a suitable foundation leads to personal limitations which are difficult to overcome and are apt to hamper the usefulness of the individual not only to himself but also to the community at large.

One of these books is by an English author; the other is by an American. The shock is, therefore, not so great when one reads in the preface to the American book that chemistry is a branch of the engineering profession.

We in Great Britain are still in the throes of producing a chemical engineer or an engineering chemist fully armed and equipped from out of our universities, and we are not yet all agreed as to how it can best be done in the time available, or as to whether the engineer is to be superimposed on the chemist or the chemist on the engineer. Indeed, many of us think that

the term should only be applied to those chemists who have had at least five years' works practice. In the United States there appears to be no such problem, and many of the universities in that country have granted degrees in chemical engineering for some time past.

(1) In his introduction to the series of monographs on industrial chemistry, Sir Edward Thorpe stated definitely that "they will serve to show how fundamental and essential is the relation of principle to practice," and, now that seventeen volumes of the series have appeared, it is possible to realise how closely this wise provision has been followed. It is sometimes urged by reviewers and others that the volumes do not deal with industrial chemistry at all, but are merely compilations of academic interest. This is not the case, and the present volume by Dr. Spielmann is an instance in point. It was not intended that these volumes should "cover the whole ground of the technology of the matters to which they relate" or be "concerned with the technical minutiæ of manufacture except in so far as these may be necessary to elucidate some point of principle." They are intended for the use of chemists in the real sense of the word, whether academic or industrial, who wish to acquaint themselves with the general practice and most recent development of the branch of applied chemistry under treatment. In these ways Dr. Spielmann's book is a notable addition to the series and will be welcomed by all who desire to follow the most recent advances in coal tar chemistry.

The book is well printed and the formulæ are clear, but to any reader who is not an expert organic chemist they may cause trouble, because there appears to be no uniformity of treatment. For example, sometimes the formulæ are written in full as in chrysene (p. 103), sometimes in abbreviated form as in naphthacene (p. 104) Often the aromatic nuclei are represented as simple rings without adornment (naphthalene, p. 72), often the Kekulé double valencies are included (quinaldine, p. 159). Sometimes hydrogen atoms are placed at the angles of the benzene hexagon either without the double valencies (coumarone, p 135) or with them (indene, p. 73). The effect even on the expert reader is apt to be irritating, and the author might well consider an alteration in this connexion for future editions Had this book been discovered in Tutankhamen's tomb and constituted the sole evidence of the type of graphic formulæ used by the ancient Egyptians, no Rosetta stone would have enabled modern men of science to solve the problem.

(2) It is stated in the preface of Mr. Groggins' work that this book is intended "for the student of chemical engineering as well as the graduate engineer or works chemist." It is not clear if the "or" in the above sentence implies that the last two terms are synonymous, but, in any case, it is certain that the author intends his book to appeal to a wide circle. It constitutes a sharp contrast to Dr. Spielmann's book, which is written essentially for the educated chemist and would, in all probability, prove irksome to the usual engineer manager In other words, it is an outcome of the view that the engineer without fundamental chemical training can be supplied with a sufficient working knowledge of the chemistry and physics of a process to enable him to carry through without the aid of a competent chemist. The book is, therefore, replete with drawings of plant and the technical minutiæ of aniline manufacture.

It is not the writer's object to quarrel with the method employed, but only to wonder if a book of this kind is really of educational value or whether it is not rather a book of reference. So far as the treatment is concerned it is admirable, and it represents the last word in the technology of aniline manufacture. The chemical theory is a bit scrappy, and if a firm were to rely on the technical information supplied in order to start the manufacture of the base it would, in all probability, have spent all its spare capital long before it had decided on which process to adopt. Nevertheless, as a record of the chief processes involved, the book is of real value, and of special importance and utility are the chapters on cost factors (p 91), and on thermal factors (p. 104), for these are matters, essential to engineers and chemists alike, to which too little attention is given; the article on the chemist's budget (p. 97) is particularly noteworthy and will well repay attention. The chapter on aniline poisoning (p. 117) provides some startling facts, and that on general chemical and physical data (p. 131) gives information not readily available elsewhere. The book is readable and well set up. It should be read by all who have an interest in the subject with which it deals.

J. F. T.

The Teaching of Physiology and Pathology.

(1) *A Text-book of Physiology.* By Prof. H. E. Roaf. Pp. viii+605. (London: E. Arnold and Co., 1924.) 25*s* net.

(2) *Text-Book of Pathology.* By Prof. Robert Muir. Pp. vii+774 (London: E. Arnold and Co., 1924.) 35*s*. net.

(1) PROF. ROAF'S volume is based on the course of instruction given at the London Hospital Medical School, and represents, presumably, a scheme for the presentation of the facts of physiology which he has found to be more satisfactory in its results than the traditional method, for it marks to some extent a new departure in text-books on the subject.

Hitherto it has been usual to consider as a group or system those organs of the body which act together for a common end. Thus the physiology of the alimentary system has embraced a description of all those organs the main function of which is to bring about digestion and absorption of an animal's food. They have been compared and contrasted as regards their structure, function, and the means whereby their function is regulated in order to further the ends for which they are designed and to assist in the co-ordination of the body as a whole. In the work under review this method is not adopted, but, instead, the subject of animal physiology is approached from the point of view of the chief activities which an animal displays Mechanical aspects are dealt with in the first section, chemical activities in the second, regulative mechanics come next and occupy the largest section of the book, and, finally, a special section is devoted to the maintenance of the individual and reproduction.

However logical this method may appear in theory, it is not always satisfactory in practice. If there is one subject more than another in physiology in which the thermal, chemical, electrical, and mechanical phenomena associated with its action have contributed as a whole to the understanding of its mechanism, it is that of muscle. It would seem best, therefore, in dealing with the physiology of muscle, to consider these phenomena in succession in order to show what light each has thrown on the working of a muscle. This, however, has not been done. The thermal, mechanical, and electrical changes are described in one section and chemical changes in another, where they are grouped with processes of absorption, excretion, and secretion, with which they have little in common except that in each there is a degradation of energy. Other examples illustrating the difficulties of this scheme of treatment might be given On the other hand, there is much to be said for a book modelled on these lines, in that it gives the student a new point of view and directs his attention to fundamental likenesses in many aspects of bodily activity which might well escape him in reading text-books written on more familiar lines. Were the book a text-book of general physiology, then it could certainly be conceded that the method of treatment adopted by the author is the right one.

Here and there some lack of perspective is shown regarding the space devoted to certain subjects. For example, the reaction of sugars with phenyl hydrazine is spread over a page and a half, whereas the depressor nerve and its functions receive only half a page. The book is well illustrated and contains some new and useful diagrams.

(2) Prof. Muir's book is founded on the course in pathology given at the University of Glasgow. The earlier chapters deal with general disturbances of nutrition and of the circulation, the phenomena of inflammation and its sequelæ, and infection, immunity, and fever. Then follows a section devoted to the description of tumours and their causation, and finally, the lesions which are met with in the various systems of the body—circulatory, respiratory, alimentary, etc. —are discussed. Although there is thus a division of the subject into general and special pathology, it is not apparent in reading the book that any real separation under these two heads occurs. That is one of its virtues. It is sometimes said that pathology is the study of physiological processes which have "gone wrong," and there is a good deal of truth in this somewhat bald statement What it implies is that many phenomena met with in pathology are really the result of physiological reactions proceeding, it may be, to excess or in an abnormal direction Prof. Muir rightly emphasises this in his introduction, and, what is more, makes practical application of it in his method of teaching. Wherever one turns in the book, this underlying idea can be discerned. We feel, therefore, that the student who has just completed his course in physiology and has then begun his study of pathology, guided by this book, will find a natural sequence in description, explanation, and discussion which is too seldom met with in books devoted to subjects of the medical curriculum The book thus makes a useful bridge to the gap, which in the past has been too apparent, between the subjects of the second M.B. examination and those of the later period of the medical student's course.

Accounts are given in appropriate places of the investigation of pathological processes by other means than the microscope. This instrument has rendered inestimable services in the past and it will no doubt do so in the future, but other methods are available as adjuncts to it, and the experimental investigation of pathological processes is likely to be fruitful in helping to elucidate the initial causes of disease and to explain disturbances of function which result from them. The discussion of the results of such methods is not common in text-books of pathology and is therefore to be commended.

The book is admirably proportioned and the illustrations are one of its special features. The author is to be congratulated on them. They are all reproductions of photographs which have been made with great technical skill, and it is obvious that they have been carefully selected. We feel sure that the book will be widely welcomed by both students of medicine and those engaged in teaching and clinical practice.

H. S. R.

Our Bookshelf.

PSYCHOLOGY.

Crime and Insanity. By Dr. W. C. Sullivan. Pp. vii+259. (London: E. Arnold and Co., 1924.) 12*s.* 6*d.* net.

As Medical Superintendent of Broadmoor Asylum, Dr Sullivan is in a position to speak with authority on a subject which is now arousing considerable interest, not only in medical men and jurists, but also among the general public. There is no lack of literature dealing with disorders of conduct from the point of view of the alienist, and with criminal responsibility of the insane considered on the standards imposed by the law. The efforts of the author of "Crime and Insanity" have been directed towards presenting the abnormalities of conduct which are dependent on mental disease, as clinical features demanding a study of their nature and origin, and this book is a proof that when approached on these lines, the more special question of criminal responsibility becomes less complex and loses much of the obscurity with which legal subtleties have cloaked it.

Responsibility is rightly recognised as being a purely legal question, the law expresses the attitude of the ordinary man of common sense, living at this time and in a particular country. The McNaughten rules, which are always applied as the law of England, though they bear the dignity neither of parliamentary enactment nor judicial decision, enunciate the opinion of the bench of judges in the year 1843. It must be agreed that they do not represent the general feeling of public opinion to-day, and it is widely recognised by lawyers and medical men that they are inadequate; their interpretation by judges is variable and they are rarely applied rigidly. Dr. Sullivan points out that the test is unsatisfactory because it is based on a misconception of the facts; he advocates the adoption of a simpler test of responsibility, the admission of qualified responsibility, and the establishment of a system for providing the court with expert evidence concerning the mental state of the accused.

Most of this book is devoted to clinical material, and there are numerous descriptions of cases illustrating the criminology of the various types of mental disorder. It is an important and practical contribution to the literature of insanity.

VIIth International Congress of Psychology, held at Oxford from July 26 to August 2, 1923, under the Presidency of Charles S. Myers. Proceedings and Papers, edited by the President. Pp. xxv+388. (Cambridge: At the University Press, 1924.) 12*s.* 6*d.* net.

THE various papers collected in this report have a high intrinsic value, but the greatest interest of such a collection is to be obtained by comparing the different points of view rather than by studying the individual contributions. The discerning reader can thus obtain a trustworthy insight into the recent progress of psychology, a knowledge of its present position, and even perhaps a prognostication of its future development. The collection is representative of modern psychological thought, containing, as it does, papers from most of the leading British psychologists and from many eminent foreigners. The editorial succeeds in emphasising the cordial international relationships which were so evident to all who attended the congress, but it seems unfortunate that no allowance was made for British linguistic ignorance by adding an English summary of the foreign papers.

Particularly interesting to the general reader are the various symposiums—"The Nature of General Intelligence and Ability," "The Conception of Nervous and Mental Energy," and "The Principles of Vocational Guidance"—but where there are so many valuable papers it seems invidious to particularise. All who wish to be abreast of the times in psychological thought will find this volume a necessary addition to their shelves.

Special Talents and Defects: their Significance for Education. By Prof. Leta S. Hollingworth. (Experimental Education Series.) Pp. xix+216. (New York: The Macmillan Co., 1924.) 7*s.* 6*d.* net.

OUR eyes turn naturally towards the unusual; the one exception to the rule is often more interesting to study than the ninety-nine corroborating cases. There is certainly scientific value in such a study, for a fruitful suggestion is often obtained by comparing the normal with the abnormal to find their common factor.

Prof Hollingworth writes of the exceptional child who shows a particular gift or deficiency in some scholastic subject not to be expected from his general mental level. The subject is introduced by a helpful discussion on the nature and causes of abilities and of their inter-relations, and then proceeds to a consideration of the neural base involved. The main part of the book is devoted to a detailed presentation of extreme variations of ability in the ordinary school subjects. A chapter each is given to reading, spelling, arithmetic, drawing, and music; cases are cited, and causes and remedies are discussed.

Every teacher of experience has met children who astonished him by some such unexpected gift or defect. This book is valuable for its clear explanations and practical advice in connexion with such phenomena.

NATURAL HISTORY.

(1) *Everyday Doings of Insects.* By Evelyn Cheesman. Pp. 245. (London, Calcutta and Sydney: G. G. Harrap and Co., Ltd., 1924.) 7*s.* 6*d.*

(2) *The Great Little Insect.* By Evelyn Cheesman. Pp. 256. (London: Hodder and Stoughton, Ltd., 1924.) 6*s.* net.

THESE two books, as may be gathered from their titles, are written essentially for the instruction and entertainment of lay readers. Their author, who is curator of insects at the Zoological Gardens at Regent's Park, London, is well qualified to enlighten the public as to many of the facts and theories respective to insect life. In her official position she is enabled to judge to a large extent what type of book will meet the demands which she is catering for. Both volumes are written in a clear, attractive style and with a "freshness" that comes as the result of a first-hand acquaintance with the objects concerned.

(1) The little book entitled "Everyday Doings of Insects" is written with the intention of supplying answers to some of the questions that are often asked concerning the exhibits in the Insect House at the Zoological Gardens. It is more especially addressed to boy inquirers with the view of encouraging their interest in entomology. The photographs and sketches have been made from the living insect in almost every case, and they add greatly to the attractiveness of the volume.

(2) "The Great Little Insect" is intended for older readers, and consists of a series of essays discussing various activities of insects and the laws which we believe govern them. In these chapters the author has brought together many facts which, although well known to the entomologist, seldom reach the lay public Such facts are weaved together in an interesting manner, and the volume is a fascinating one for the fireside reading of winter evenings.

Illustrations of the British Flora: a Series of Wood Engravings, with Dissections, of British Plants. Drawn by W. H. Fitch, with additions by W. G. Smith and others. Fifth revised edition. Pp. xxvii + 338. (London: L. Reeve and Co., Ltd., 1924.) 12*s.* net.

THE appearance of the fifth revised edition of the "Illustrations of the British Flora" completes the republication of "Bentham's Handbook of the British Flora." It is universally acknowledged that both the text (now called the Handbook) and the illustrations have been of great use to several generations of botanical students, especially beginners. It is, however, unfortunate that the two volumes have been reissued without more drastic alterations having been made. A considerable number of serious mistakes are perpetuated, as, for example, in Fig. 933, where the leaves of *Populus canescens* are figured as *P. alba*, and in Fig. 935, where the catkins of one species and the leaves of another are figured under the name of *P. nigra*.

The common vernacular names and, for many species, a letter to indicate the flower colour have been added to the botanical names for each figure. A new index has been compiled, giving, in single sequence, the generic and common names. A summary of family characters and an analytical key to the families and anomalous genera are reproduced from the Handbook. Several new figures are incorporated, but they are not up to the standard set by Fitch.

The Teaching of Biology in Schools and Training Colleges. By Ethel M. Poulton. Pp. xv + 112. (Birmingham: Cornish Bros., Ltd., 1924.) 5*s.* net.

BIOLOGY, as here considered, is not that of the specialist in zoology or botany, but rather that for which a place is claimed in the general education of all pupils, and especially of those in primary and secondary schools. In addition to minor, but not unimportant, objects, the chief aim of such general biology is rightly stated to be the stimulation of interest and curiosity, and to produce enjoyment, both æsthetic and intellectual, of Nature. The opening chapters of this useful little book contain an eloquent *apologia* of biology, based upon a consideration of its values and aims, and of the psychological factors which should influence the selection of material and the methods of teaching. The teacher who would be ready to give an answer for his faith in biological teaching will find here his brief set out in excellent style. In subsequent chapters the author has constantly in mind the students at training colleges. Though, perhaps, she says nothing that is entirely new on courses of Nature study and the more advanced work, she has nevertheless done good service to all teachers of biology in bringing together, and more or less codifying, the general principles by which all should be guided, and not less in pointing out the many pitfalls that beset the path of the inexperienced. Stress is very properly laid on the importance of presenting biology as a study of *living* things.

BACTERIOLOGY.

Practical Bacteriology: an Introductory Course for Students of Agriculture. By Andrew Cunningham. Pp. vii + 188. (Edinburgh and London: Oliver and Boyd, 1924.) 7*s.* 6*d.* net.

A LARGE amount of information is contained in this small book, which is well planned and very readable. Bacteriological technique is described in the earlier sections: preparation and sterilisation of culture media, the use of the microscope, and staining methods and cultivation. A series of exercises then follows, each dealing with some particular subject or process, and so arranged that the student becomes familiar by easy stages with bacteriological methods

The bacteriology of milk and dairy products, of soil and manure, is then similarly dealt with, some of the special reactions applied to milk being also included, namely, the catalase, curd, and other tests.

In the final chapters some of the more important bacterial plant and animal diseases are described, and classification and formulæ are given in appendices. The practical exercises for the most part are simple and easily carried out in a short time, and have been chosen with commendable discretion; any one who worked through the lessons with some supervision should possess a considerable grip of bacteriology. The book is well produced and illustrated

Elements of Water Bacteriology: with Special Reference to Sanitary Water Analysis. By Prof. S. C Prescott and Prof. C E. A. Winslow. Fourth edition, rewritten Pp. ix + 211. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1924.) 11*s.* 6*d.* net.

THE work under notice is, on the whole, an excellent monograph on water bacteriology. First published twenty years ago, the present edition has been revised throughout. The procedures outlined are those of the Committee on Standard Methods of the American Public Health Association, and in some respects differ from those current in Great Britain. Chapters on the bacteriology of sewage and sewage effluents and the bacteriological examination of shell-fish are included. Much information has been collected on *Bacillus coli* and its variants and methods for their detection and isolation, though some of the fermentation reactions of the allied organisms are incorrectly given. One of the most important chapters is that on the significance and interpretation of bacteriological examinations of water, and the position taken is a thoroughly sound one. A bibliography running into twenty-nine pages completes this useful book.

Louis Pasteur. By Prof. S J Holmes. Pp. vi+246+4 plates. (New York: Harcourt, Brace and Co, 1924.) n.p

THIS short biography gives all the essential facts of Pasteur's life and work. Commencing with his early days, the salient features of his researches and discoveries are summarised in chronological order, and for the uninitiated reader explanatory paragraphs are introduced where necessary. The text is very readable, and is illustrated with several figures and some good portraits. A sympathetic account is given of the celebrations on Pasteur's seventieth birthday and of his last days, and we leave the great veteran sleeping in the beautiful little chapel in the basement of the Pasteur Institute, where "four angels watch over him, Faith, Hope, Charity, and Science, and in the laboratories above his tomb, his great work is going on."

METALLURGY.

Practical Microscopical Metallography. By Dr R. H Greaves and H. Wrighton Pp. x+125+28 plates. (London. Chapman and Hall, Ltd., 1924.) 16*s.* net.

THE authors state in their preface that their intention is "to provide, within a small compass, a set of typical photomicrographs suitably annotated and accompanied by an account of such related matters as might profitably occupy the minds of students during the necessarily long hours—many of them spent in purely mechanical operations—devoted to microscopical work," and that the book is intended both for metallurgical students and for students of engineering who study metallography.

We feel some doubt as to whether the book will be found useful. So far as metallurgical students are concerned, it is so restricted in scope that it could not serve as an adequate introduction even to microscopical metallography None of the chapters deal with the construction of the equilibrium diagram and thermal methods of investigation which, in conjunction with microscopical work, constitute the experimental data on which the diagrams are based. With respect to engineering students, it is necessary to face the fact that the properties of any metal or alloy cannot be deduced from its microstructure. The polyhedral structure, characteristic of a pure metal, holds equally for tough and ductile metals on one hand, and for brittle metals on the other Even the most skilled metallographer confronted with a photograph representing the microstructure of a metal or alloy, of the chemical composition of which he was unaware, could say very little about the mechanical properties it would be likely to possess. We doubt whether any student of engineering, in the absence of previous knowledge of the subject, could grasp the real implications of the equilibrium diagrams reproduced in the book, and whether he could form a true mental picture of the facts which they convey It seems to us that the book cannot do much more than awaken an interest on the part of metallurgical and engineering students in the subject of microscopical metallography, and a desire to study the subject in a much broader way such as is afforded by one of the numerous text-books of metallography already available.

The Planning, Erection, and Operation of Modern Open-Hearth Steel Works. By H. Hermanns. Pp. vii+307 (London: Ernest Benn, Ltd., 1924.) 42*s.* net.

MR. WESLEY AUSTIN has performed a valuable service to English metallurgy in translating Mr. Hermann's important work on the planning and operation of modern open-hearth steel works. Technical literature is rich in works which concern themselves with descriptions of the metallurgy of steel production in open hearths. The auxiliaries, however, which serve to carry out the metallurgical work and to lighten or cheapen the mechanical operations, have been given only secondary attention. They are of equal economic importance to the processes, and in great measure not only render these possible, but also assure their efficiency. The point driven home in this book is the economy which results from excellences in furnace design and equipment, from attention to practical expediencies in the general arrangement of plant, and from a careful lay-out of storage, handling, and transport facilities Every type of equipment for open-hearth steel production is described in detail and very clearly illustrated, not only from Continental practice but also from a very close study of English and American practice. The book is intended on one hand for the steel works staff and managers and, on the other hand, for technical and higher grade students. In addition, it should provide hints for designers and draftsmen. It is abundantly illustrated by clear drawings, which are one of the best features of the book. We think that Mr. Hermann's work would repay careful study by the management of every open-hearth steel works in Great Britain.

Arc Welding Handbook By C. J. Holslag. Pp. xi+250. (London: McGraw-Hill Publishing Co., Ltd., 1924.) 10*s.* net.

THIS book is intended to serve as a simple and practical manual of instruction in arc welding. An attempt has been made—and made successfully—to describe the methods step by step in a clear and practical manner so that the beginner may understand both the equipment and the processes. The author has also kept in mind those men who may supervise the work, so that there may be no mystery to them about what the welding operator is trying to accomplish. The book is very clearly written and illustrated by numerous figures

The early chapters deal with the various types of welds that can be produced. Regard is paid both to thin and heavy sections. We have found the chapter on the welding of cast iron and malleable iron particularly interesting. There is an illustration on p. 125 of a 15-ton cast iron gear housing which had been broken in eight pieces and was afterwards mended by arc welding. A total length of 190 feet of welding 1½ inches thick was required. Considering the brittleness and low tensile strength of such iron, this must be regarded as a remarkable achievement. Later chapters deal with the welding of structural steel, sheet iron and non-ferrous metals, electric arc cutting, and the welding of alloy steels. The book is full of useful information and may be heartily recommended to those for whom it is intended.

First (Experimental) Report to the Atmospheric Corrosion Research Committee (of the British Non-Ferrous Metals Research Association). By W. H. J. Vernon. Presented to the Faraday Society, December 17, 1923; with Full Report of Discussion. Pp. 839-934. (London: The Faraday Society, 1924.) 7s. 6d. net.

THE research by Mr. W. H. J. Vernon on the tarnishing and fogging of metals, presented to the Faraday Society on December 17, 1923, of which some account has already appeared in our columns (NATURE, February 2, 1924, p. 178), has now been published with a full report of the discussion which took place on that occasion, together with certain communications since received. The discussion is of a thoroughly broad and representative character, and many points of view and interesting items of information were contributed. Mr Lancaster mentioned that although it was generally considered that the purest zinc was the most difficult to dissolve in acids, Mr. Rigg, late of the New Jersey Zinc Company, had found that the purest zinc they had produced for the United States Bureau of Standards was almost explosive under acid treatment; in other words, the rate of solution was very rapid. Taken as a whole, the discussion and contributions add decidedly to the value of the report, and general unanimity was expressed that the most hopeful way of solving the practical problem of preventing the tarnishing and fogging of metals was to attack it by laboratory experiments carried out on fundamental lines of scientific inquiry

ELECTRICAL ENGINEERING.

Small Electric Generating Sets Employing Internal Combustion Engines. By W. Wilson. Pp. 161+16 plates. (London: Ernest Benn, Ltd., 1924.) 18s. net.

MANY are interested in the small electric generating sets that are used for country-house lighting and for supplying electric power for kinematographs, radiographic outfits, etc., in isolated localities. The invention of the tungsten lamp and recent developments in internal combustion engines have made small installations highly desirable in many cases. Most of the books which deal with this subject are now becoming antiquated, so we welcome Mr. Wilson's volume, which describes the best modern practice.

The author has hit the happy mean between a book overburdened with elementary theoretical matter and one that goes into highly technical details, which are only of interest to the manufacturer. So far as lighting current is concerned, electricity can be generated by the consumer at a cost little more expensive than that charged by a public company. But if it is used for heating and power purposes, it compares very unfavourably with a city supply. For many purposes in connexion with farming, electricity can be economically employed. For illuminating yards, stables, and outbuildings it is most valuable, but it is essential to use suitable water-tight fittings. It has now been conclusively proved that the low productiveness of the hen during the winter months is not due to the want of heat, but to the want of light. The lack of daylight in winter can easily be made up by installing a fifty-watt lamp in the fowl-run. It is required from 5 A.M. until dawn and from dusk until 9 P.M. The switching can easily be done by an automatic device. Under these conditions the hens continue to lay almost as in summer, having the requisite time to take more nourishment.

Alternating Current Rectification: a Mathematical and Practical Treatment from the Engineering View-point. By L. B. W. Jolley. Pp. xviii+352. (London: Chapman and Hall, Ltd., 1924.) 25s. net.

THE conversion of alternating current into current pulsating in one direction is a problem which electrical engineers have been studying for many years. In the early days of the industry, a serious drawback to the use of alternating currents for supply distribution was that there was no accumulator suitable for storing the electrical energy, and hence the alternators had to run night and day. Electrolytic valves were then invented to rectify the alternating current, so that it could be used for charging cells. In polyphase systems of supply, this was accomplished mechanically by machines called rotary converters. At the present moment mercury vapour rectifiers are employed in many towns to get direct current from an alternating supply. In connexion with radio engineering all kinds of rectifiers are used. It will be seen, therefore, that the field is a wide one and it is continually expanding.

Mr. Jolley's book opens with a good discussion of wave form, and Fourier's analysis is applied to several problems in an instructive way. The mechanical rectifiers are next discussed, including a brief description of the Highfield transverter. Then we have descriptions of mercury-vapour rectifiers and vacuum tubes. Interesting descriptions are also given of point to plate discharge, vibrating flame rectifiers, corona rectifiers, and photo-electric cell rectifiers. Finally the author discusses the conduction of electricity through liquids, a knowledge of which is necessary in order to understand electrolytic rectifiers and radio rectifiers. Numerous helpful references are given to papers and books. The book can be recommended to research engineers.

Railway Electrification: a Complete Survey of the Economics of the Different Systems of Railway Electrification from the Engineering and Financial Points of View. By Prof. H. F. Trewman. (The Specialists' Series.) Pp. xii+244. (London: Sir Isaac Pitman and Sons, Ltd., 1924.) 25s. net.

THIS book gives a survey of the economics of the different systems of railway electrification from the engineering point of view. It is pointed out that for the last thirty years electricity has been successfully employed all over the world to operate tramways. At the beginning of the century it was adopted for elevated and tube railways. Then came the electrification of the suburban railways, and finally, mainly on the Continent and in the United States, the electrification of the main line railways. It is universally admitted that electrification of the main line railways in Great Britain is feasible; the only question about which opinions still differ is the financial one. Were it not for the War, at least two British main lines would have been rapidly extending their systems of electrification. Apparently they have adopted a policy of waiting, and so we are continuing to burn an unnecessary quantity

of coal Many who have considered the problem with great care are in favour of electrification. This book is written for engineers and contains much valuable data from the point of view of the economics of the problem, but we think that the author could have made out a stronger case for electrification. There are not many cases—we know of none—where a railway once electrified has gone back to steam locomotives, but we do know that the electrical staff on most of the English railways is in ludicrous disproportion to the mechanical engineering staff. In Chapter ii. the author states that it can be proved mathematically that the best site for a power house from the point of view of transmission costs is the centre of gravity of the load. This theorem has been recently proved to be erroneous. It requires the unwarrantable assumption that the percentage loss of power in the minimum case is the same for all the distributing mains

MISCELLANEOUS.

Animal Nutrition By Prof T. B Wood Pp viii + 226 (London: University Tutorial Press, Ltd., 1924) 4*s.* 6*d*

THE issue of a text-book on animal nutrition from the Cambridge Research Institute marks a new era in the application of science to the feeding of live-stock in Great Britain For so many years have we been in thrall to German and American literature that to be in possession at last of an authoritative work of native origin, however modest its scope and pretensions, induces feelings so pleasurable as largely to disarm criticism. We hope that the present modest volume may be regarded as but the forerunner of the more ambitious and comprehensive works that should follow in due course from the Cambridge workers

It is a companion volume to Prof Wood's "Chemistry of Crop Production," these works being admittedly of elementary character, and although designed to meet the needs of the elementary student, bear obvious signs that the possibility of a circulation amongst advanced farmers has not been entirely outside the mind of the writer This dual aim would seem to have a strong fascination for the agricultural writer —or does the pressure come more from the side of the publisher?—and the result is rarely entirely satisfactory to either class of reader. Few writers possess the genius of Prof Wood for this class of work, but we venture to think that even he has only attained his end through some sacrifice of the interests of each class of reader Had he been writing solely for the student, who is assumed to have some knowledge of chemistry, he would doubtless have given a rather more advanced treatment of the subject matter of his introductory chapters, whilst a great deal of the detailed experimental work that is embodied in the text might also have been more usefully collected into an appendix or a separate practical manual. For the farmer reader, on the other hand, much of this experimental work must necessarily be unintelligible and consequently redundant These criticisms, however, in no way preclude a very favourable opinion upon the treatment of the subject. In his later chapters, in which he turns to practical applications, Prof. Wood is excellent, and this part of his book will be read and used by a far wider circle of readers than that for which it is primarily intended. Special reference may be made to his extension to fattening animals of the system of "rationing by performance," which is proving so successful in the case of dairy cows. This is a very real advance, for which all concerned with the difficult task of giving advice on practical feeding problems will be grateful.

The book is well produced and issued at a low price, and may be warmly commended to all agricultural students and others concerned with the feeding of live-stock.

Clockmaking, Past and Present. With which is incorporated the more important portions of "Clocks, Watches and Bells," by the late Lord Grimthorpe, relating to Turret Clocks and Gravity Escapements. By G. F. C Gordon. Pp viii + 232 + 35 plates. (London: Crosby Lockwood and Son, 1925.) 16*s* net.

To the makers and lovers of clocks this volume will be a welcome addition to their bookshelves. Though not intended to be a complete treatise on the subject, the author deals systematically with the materials, tools and mechanisms of clock-making and gives much excellent advice. The plates are a notable feature of the book, and though naturally most of them are devoted to various forms of clocks and clock cases, not the least interesting are those illustrating wheel-cutting machines, pinions and their collets, new and old screws, and the clock hands of various periods. There is one omission that should be pointed out On p. 58, when dealing with compensation balances, it would have been well to explain that the necessity for compensation arises mainly through the change in the elasticity of the spring of the balance due to alteration in temperature, and not through the variation in the dimensions of the balance.

There is a good chapter on the question of restoration and repairs to clocks and clock cases. In a short note on British clocks for export, the author offers some criticism of clocks sent abroad, and suggests that if the British Horological Institute were to issue designs and detailed specifications for three or four types of clocks, it would confer a great benefit on all concerned A bibliography is given containing some 80 or 90 books and pamphlets on clocks published since the appearance of Derham's "The Artificial Clockmaker" of 1696.

Around the Horn to the Sandwich Islands and California, 1845–1850. Being a Personal Record kept by Prof. Chester S Lyman. Edited by Prof. F. J. Teggart. Pp. xviii + 328 + 16 plates. (New Haven: Yale University Press; London: Oxford University Press, 1924.) 16*s* net.

PROF. C. S LYMAN was connected with Yale University for thirty-two years as professor of physics and astronomy and director of the observatory. He died in 1890 at the age of seventy-six. This book is the diary which he kept as a young man during several years in the Sandwich Islands and California. The long sea voyage round Cape Horn occupies only a few pages. His observations on the people of the Sandwich Islands are of value as a record of past conditions, and there is a good account of the volcano of Kilauea. Most of the diary has little scientific interest, though some of the descriptive matter is vivid. There are many interesting illustrations taken from old prints.

The Exploded Ether.

THE idea of a universal physical æther seems to be getting terribly in the way According to Dr Jeans, in the Supplement to NATURE of March 7, p 362, "It was something more than a coincidence that Newton, Kelvin, Clerk Maxwell, and Faraday [the advocates of an æther] were all British, while Boscovich, Einstein, and Weyl are not" Descartes is not mentioned

One notices that the reason for supplanting Maxwell by Weyl is based on the original form of "Weyl's electromagnetic theory," which aims at absorbing electric fields into space—a theory which Einstein has steadily and consistently rejected, for the reason that its "two-foot rule" changes its length as it wanders through space, so that when it comes back to its starting-place it does not recover its original length, and (metaphorically) you don't know where you are.

Seizing on an idea of Eddington's, and utilising the Principle of Minimal Action, which is fundamental in physical formulations, Einstein has himself developed a theory analogous to Weyl's but he has to admit that it cannot in his hands explain electricity by atomic electrons It has, however, been claimed by another investigator that this can be got over by use of a widened foundation, and the question perhaps deserves further scrutiny by experts A quotation is here relevant, from Prof De Donder of Brussels, the most recent exponent of this interesting but very complex algebraic analysis. "En lisant les trois notes qu'Einstein a consacrées à la gravifique de Weyl-Eddington, on remarque que la confiance que lui inspire cette théorie va en diminuant C'est ce qui m'a conduit à lui demander son avis actuel, afin de pouvoir le communiquer au cours de mes conférences à la Sorbonne J'extrais de sa lettre (Leiden, 4, XII 1923) la phrase très importante 'Deshalb neige ich jetzt dazu, der ganzen theoretischen Entwickelung, welche auf einer Verallgemeinerung der Riemann'schen Metrik durch Verallgemeinerung der $\Gamma^{\sigma}_{\mu\nu}$ beruht, überhaupt keine *physikalische* Bedeutung beizumessen'"

If there is a distinctively British view of the æther, it is the one that was promoted, in his usual fragmentary and erratic manner, by Kelvin, the inspirer, along with Faraday, of Clerk Maxwell It identifies the æther as the substratum, with physical qualities, in which all matter subsists as a limited number of possible types of atomic structures, and which, moreover, binds these discrete atoms into a cosmos by their necessary interactions across it. Being the medium which makes atomic matter possible, it is not itself matter, and is not limited by any analogy to matter. It makes no essential difference whether one visualises it as an active physical medium or alternatively describes it as "space," or a "fourfold extension," endowed with physical qualities. The earlier analogies introduced waves of light and the electric field by contemplating displacement of the small parts of the æther, a varying displacement involving strain with its energy of elastic deformation. The newer representations become feasible through introducing the cognate notion of "parallel displacement" of the varying "space," as defined by the algebraic formulations of Prof. Levi-Civita. The relevant problem, as above indicated, is to carry the ideas through as far as possible, and so test the extent and appropriateness of their analogy with physical reality.

Fundamental space and time ought, one would think, to be uniform, the same everywhere As soon as the qualities of space are made to depend on the presence of adjacent portions of matter, it ceases to be pure space and becomes an interconnecting medium with physical properties But this subject, on its epistemological side, is far from having yet been exhausted. JOSEPH LARMOR

Cambridge, March 7.

Ether and Matter and Relativity.

IN the most valuable supplement to NATURE of March 7, through his Kelvin lecture to the Institution of Electrical Engineers, Dr Jeans gives a splendid summary of the present position in physics, showing how Lord Kelvin's "two clouds" obscuring the connexion of radiation and matter, instead of dispersing, have expanded to fill our scientific vision. Incidentally, Dr. Jeans makes it clear that in his view the terms ether and force are unnecessary, since all that they connote can be represented equally well by pure geometry, and indeed much better than by Lord Kelvin's curiously mechanical mode of attack. It is marvellous what hyper-geometry can be made to express, and what high reasoning about reality can be thus carried on But here comes the point I suppose that much the same can be said about the non-necessity of the idea of matter That too can be expressed geometrically, and apparently dealt with analytically, as the impenetrable centre of a warp in space, and as $G^{\nu}_{\mu} - \frac{1}{2}g^{\nu}_{\mu}G$, an expression which Prof. Eddington says behaves exactly like matter, except that it is more continuous than atomic, adding that the mind could scarcely recognise anything simpler as substantial and permanent ("Math Theory of Relativity," p 120) If relativists will grant that ether and matter can be *equally* dispensed with, a supporter of the ether need have no conflict with them. for ultimate questions about reality and existence can be left to philosophers.

OLIVER LODGE

The Source of Stellar Energy.

THE source of a star's energy is debated in recent letters by Prof. Lindemann and Dr Jeans (NATURE, Feb 14 and 28). Dr Jeans's conclusion is that the liberation of energy from the sub-atomic store occurs at a rate independent of temperature and density, and if one star liberates energy more slowly than another, it is solely because the former has exhausted the more prolific material. I think that there are grave astronomical objections to this view

First, it requires that the rate of emission of radiation by the star shall be very largely dependent on its previous history, whereas the astronomical indications are that it is so closely correlated to the present mass that there is little scope for outside factors. Consider, for example, two stars, each of which has radiated $\frac{1}{2}$ of its original mass, so that they are in the same stage of exhaustion: the first, originally of mass 3, is now of mass 1; the second, originally of mass 12, is now of mass 4. Their rates of radiation should accordingly be in the ratio 1 : 4; but both theory and observation seem to show that a star of mass 4 always radiates much more than 4 times as strongly as the sun

Secondly, this hypothesis seems to make the stars unstable. The energy E which is liberated must be

got rid of by radiation, and the radiation L is fixed by the mass and (to a comparatively small extent) the radius of the star. By hypothesis, E cannot be altered by a change in the physical conditions, so that the star must adjust its radius to bring L to the right amount. If initially $E > L$ the star is gaining energy and therefore expanding, the physical theory indicates that an increase of radius diminishes L, so that the discrepancy becomes worse. The star expands indefinitely.

The first objection is particularly evident when applied to the components of double stars which must contain material of the same age and, therefore, of the same degree of exhaustion. The hypothesis requires that these shall emit energy proportionately to their masses—a result which is not verified. The particular case of the sun and the earth is referred to by Dr Jeans, who meets the objection with a suggestion that the material forming the earth was not an average sample of the material of the sun at the time of separation. A short time ago I would have admitted this possibility; but I have recently found (in an article in the *Observatory* for March) that the rotation of a star must necessarily lead to circulatory currents in the interior which would keep the material well mixed. The argument is based on an extraordinarily general formula discovered by H. von Zeipel, and I do not think the conclusion can be evaded. It follows that when a star divides, each part has the same chemical composition, and if Jeans's rule were true the two parts would continue to be similar through all subsequent time.

It is very difficult to find a law of liberation which will satisfy astronomical requirements. In abandoning the contraction hypothesis we seem to have jumped out of the frying-pan into the fire—not that I see any conceivable prospect of returning to our former refuge. A direct dependence of the rate of liberation on density and temperature seems to be ruled out. On calculating the numerical magnitudes concerned (after taking into account all possible exhaustion-effects), it is found to give the star a kind of over-stability which would rapidly magnify the smallest disturbance into a large pulsation. This pulsation is supposed to occur in cepheid variables, but these are limited to a well-defined range of mass and density. With the hypothesis here considered cepheid variation would be more widespread.

At present, I see no insuperable objection to the following hypothesis, I scarcely recommend it in its present form, but some theory on these lines seems to be the one way out of an almost hopeless deadlock. We must consider two processes: one of evolution, the other of disappearance, of certain destructible forms of matter. The former is supposed to be dependent on density and temperature; the latter to be independent. It must be understood that the two processes are not the reverse of one another. The first is a transmutation absorbing or releasing comparatively little energy, the second is an annihilation of matter releasing great quantities of energy. The first is a synthesis involving the bringing together of constituents, its rate therefore depends on physical conditions. The second is a spontaneous degeneration in which only an isolated atom is concerned. The destructible elements are supposed to have lives ranging from a few minutes to many years, but most of the released energy comes from the long-lived products. A quiescent star will be in a steady state, except for the slow alteration of mass, the amount of self-destroying material and consequent generation of heat is thus dependent on temperature and density. Pulsation of the star will affect the rate of liberation only through the short-lived products; it should thus be possible to obtain stability without over-stability. It is necessary to admit exhaustion-effects also in this scheme, in order to reconcile, for example, the rapid liberation of energy in Capella with the slow liberation in the sun, notwithstanding the higher temperature and density in the latter.

I believe it is widely thought that the comfortable phrase *sub-atomic energy* ought to make the astronomer entirely happy, it gives him a long enough time-scale, and all is plain-sailing. Attempts to guess the *modus operandi* are regarded as mere speculation in an unlimited field. No doubt it is highly speculative to try to predict the processes by extrapolation of the modern theories of atomic physics, but the approach from the astronomical side is merely the prosaic procedure of empirically deducing unknown laws from observational data. Stellar astronomy is largely occupied with determining the rate of liberation of the mysterious source in conditions of temperature and density (both static and disturbed) which are now reasonably well known. Either the astronomer must leave this mass of data uncorrelated, or he must try to feel his way towards the disentanglement of the unknown agencies.

The Ages and Masses of the Stars.

CONCERNING Mr Schumann's comments (NATURE, January 24) upon Dr Jeans's paper (December 6) on "The Ages and Masses of the Stars," I should like to direct attention to the point of view expressed in my paper on "The Age of the Stars" which was read before the National Academy of Sciences on November 11 last, a few days before the meeting at which Dr Jeans presented his work to the Royal Astronomical Society. It was there emphasised that the decrease of mass as a result of radiation is a necessary consequence of the theory of relativity. If relativity be accepted this must be so, independently of the mechanism involved in the change of mass as *matter* into mass as *radiation*. The fact that a star radiates means that it loses mass in this way; whether all the mass lost is lost by radiation is another matter. My paper, which is to appear in the Proceedings of the National Academy of Sciences for February, goes into the point more fully than I can here.

EDWARD CONDON.

Late Palæolithic Art in the Cresswell Caves.

No one could welcome the results of Messrs Garfitt and Armstrong's exploration of Cresswell Crags more than I do myself, especially as they relieve the Palæolithic inhabitants of these islands from the unmerited reproach of an indifference to art. I only wish they had been made in time for recognition in the last edition of "Ancient Hunters."

In the light of these recent discoveries, the problem of the Cresswell "horse" assumes quite a different aspect, and I feel all the more bound to offer an explanation of the statement for which I am responsible, referred to by Sir W. Boyd Dawkins in NATURE of March 7, p. 336. It arose out of a conversation with the Rev. A. M. Mullins, rector of Langwith-Bassett, well known by his exploration of the Langwith Cavern, which is situated within easy reach of Cresswell Crags. Happening to refer to the almost complete absence of any artistic work in the Palæolithic deposits of this country, I mentioned

the famous horse as the only known exception to the general rule, when Mr. Mullins at once interposed with the remark, "And that is no exception," and proceeded to inform me that it had been introduced surreptitiously into the cave, more than one person—as I understood—having been involved in this nefarious proceeding. He demurred, however, and as I thought very naturally, to my request for names, but assured me that he spoke of his own personal knowledge.

Any reflexion on the good faith of any of the explorers of the cavern—particularly my old and dear friend the Rev Magens Mello, the actual finder of the engraving—would have at once aroused my indignant resentment, but there was no hint of this, and as Mr. Mullins's statement not only disposed finally of what I had always regarded as malicious gossip, but was also in general harmony with the state of knowledge at the time, I felt that I ought to make it public, even if only in a modest footnote

It is to be regretted that Mr Mullins is no longer with us to add his explanations to mine. All I can do now is to withdraw the controverted statement and to delete it from the footnote at the earliest opportunity

Perhaps I may be permitted to refer to another discovery which was made too late for notice in my last edition It is of great importance, since it affects not merely a locality but a whole industry I allude to the finding by M Peyrony in a Solutrean layer at Les Eyzies of a slab of limestone bearing a carving in high relief of two oxen (*Bos primigenius*) When I examined this last Christmas I was much impressed by its skilful modelling, fidelity to Nature, and artistic feeling It recalls, though less bold, the famous bisons of Tuc d'Audoubert

Hitherto the Solutrean age has afforded no objects of art, and this has always been regarded as a remarkable fact, for the Solutrean people were the first to introduce that new method in the working of flint which produced the most beautiful weapons of the Palæolithic age, and afterwards found its culmination in the wonderful productions of Neolithic Egypt and recent North America It was supposed in explanation that the Solutreans were a war-like invading race, who concentrated all their attention upon the perfection of their weapons, and had none left to bestow on purely artistic effort We now see how far this was from the truth. Transmission of Stimuli in Plants.

MR. SNOW'S letter on this subject in NATURE of January 17, p 82, suggests the following considerations:

The fact that the velocity of the movement of coloured fluids in transpiring shoots and leaves is often much slower than the transmission of stimuli can scarcely be used as an effective argument against the rapid transport of hormones in the transpiration current. When a shoot, or leaf, is cut across and supplied with stain, the whole, or most, of the cross-section of its wood may be utilised by the current, and the velocity of flow may be comparatively slow; whereas, if the water transpired is made good through a conduit consisting of one or two tracheæ only, the velocity may be very great. It is significant that Mr. Snow himself attributes the transmission of a stimulus at a velocity of 52 cm. per minute to the movement of water in the vessels (Snow, R., Proc. R.S. B, vol. 96, p. 358).

Mr. Snow refers to his Experiment 11. In this experiment the wood of the petiole of a "stem and leaf preparation" was severed by a single cut of a razor. The tension of the water in the wood was relieved by the submergence of the preparation in water, and yet, after a rest of several hours, a stimulus was observed to be transmitted across the cut to the pulvinus It still seems to me possible that the movement of the motile tissue at the base of the pinnules forced water containing the hormone through the distal tracheæ and that some of this was drawn (really pressed by the atmosphere) into the tracheæ below the cut. The continued expansion of the cells adjacent to these tracheæ by turgor would give space for this movement. Thus relief of the tension might not preclude motion in the tracheæ

In any case, the experiment requires careful confirmation It appears from Mr. Snow's description that the experiment was attempted with 40 stem and leaf preparations The exact depth of cut required, just severing the continuity of the wood, was attained in only 5 of these. Of these 5, 3 showed no transmission of the stimulus across the cut The extreme difficulty of ascertaining with certainty, even with microscopic observation, that all the water-conducting elements were cut across, and remained severed during the experiment, may justify us in suspending our judgment as to the correct interpretation of this experiment

Mr. Snow also invites attention to his Experiment 12, in which he observed that exposing a narrow zone of a petiole to steam prevented the passage of a stimulus. In his paper he points out that both Haberlandt and Fitting obtained the opposite result. Furthermore, it is quite probable that substances introduced into, or developed in, the tracheæ by the heat may have prevented rapid motion of fluids in these capillaries

With some trouble I have succeeded in consulting, at Mr Snow's advice, Prof Herbert's paper in the *Philippine Agriculturist* It has disappointed me The details of the experimental arrangements are scanty throughout, and until more convincing evidence is produced I could scarcely agree with Mr Snow's statement—"The xylem of the petiole cannot conduct excitation downward at all, as has been shown by Herbert" In fact the latter emphasises more than once that, if the downward transmission is to be prevented, "a good deal of the wood" must be removed Further, when "dexylification" was practised by Herbert, he filled the cavity left by the removal of the wood with water. In this, of course, the hormone may have been transmitted, as in Ricca's experiments.

Mr. Snow quotes Bose as having showed that the phloem is the conducting tissue, by evidence derived from electrical changes Unfortunately the same investigator produces the same evidence in favour of transmission in the parenchyma on the inner side of the xylem, mistaking it for phloem To this tissue both Snow and Herbert deny the power of transmission HENRY H DIXON

Indian Kala Azar Commission.

IN the issue of NATURE dated December 6, 1924, page 840, under a notice of the anniversary meeting of the Royal Society, mention is made of an investigation to be carried out under the auspices of that Society upon kala azar in India. The steady spread of kala azar in India has for long been a most disquieting feature in certain provinces. Recently, as a

result of the action of certain Provincial Governments in providing and encouraging treatment in the villages, the number of cases that have come forward has shown the disease to be prevalent, more particularly in Assam, Bengal, and Behar, to an extent hitherto unsuspected The number of cases treated has steadily increased as the benefits of treatment have become known, until the total for 1924 in Assam and Bengal alone has exceeded 100,000 treated cases But this probably represents only a portion of the actual incidence of the disease. There is reason also to believe that even in recent years kala azar has extensively invaded new tracts, *e g* whilst in 1910 only a few foci were to be found in Upper Assam, infection in the villages of the southern portion of this area is now almost universal There is no question, therefore, as to the menace of this disease, which has something of the relation to India that sleeping sickness has to Africa.

It may interest readers of NATURE to know that this state of affairs has received very serious attention in India, both in respect to efforts to cope with the fatal effects of infection by special measures for supplying treatment, and in regard to scientific investigation with the view of discovering the method by which the disease is transmitted Formerly kala azar was classed as an untreatable and almost necessarily fatal disease Since the discovery of the effect of tartar emetic in treatment, a large proportion of cases now yield to this drug, and the beneficent action of Governments in providing treatment has had an immense effect in the saving of life, though it has not apparently had any measurable effect in decreasing the incidence of kala azar, as was at one time hoped The scale on which treatment has been organised will be appreciated from the colossal total of treated cases already given, which represents for the greater part cases of kala azar treated near their own homes in the often remote infected villages, and cases which would otherwise have been unable to avail themselves of treatment even had the benefits of such been known to them. In Assam particularly, where the organisation for kala azar treatment has developed into one of the most remarkable efforts in ameliorative medicine in modern times, legislative measures have been freely taken, including an organisation for survey and notification and compulsory treatment where necessary The need for the latter, however, has steadily disappeared as the benefits of treatment have become known In addition, improvements in treatment which have largely originated in India promise in the future still further to rob kala azar of some of its terrors, for by the use of special antimonial compounds, *e g* urea stibamine, the percentage of successful treatments can be increased to include all but some 1·0 per cent of the 10-15 per cent of cases resistant to the ordinary method of treatment by tartar emetic. By the use of these drugs also the necessary period for treatment is reduced from a tedious period of three months to one of a month or less

Unfortunately, treatment of what is probably only a percentage of the actual number of cases, however effective to the individual sufferer, appears to hold out very little hope of preventing the continued spread of the disease, and effective preventive action can scarcely be successful until the method in which kala azar is contracted is known. The need for research on these lines has been all along appreciated in India, where, apart from the earlier work of Donovan, Rogers, Patton, Row, and others, there has been for the last ten years almost continuous investigation in the form of a Kala Azar Inquiry that has worked under officers well known as protozoologists and workers on insect-transmitted diseases. In October 1923 it was decided at the annual meeting of Research Workers of India that kala azar should receive attention as a priority research, and a draft constitution for a Kala Azar Commission was drawn up and submitted to Government. The Commission, financed by the Indian Research Fund Association and the different interested Provincial Governments, was constituted early in 1924, and has since been at work chiefly in Assam, where the facilities for the study of the disease are specially great In connexion with the Commission is an ancillary inquiry at the School of Tropical Medicine, Calcutta, constituted by Major R Knowles, I.M.S , Dr. L E Napier, and Assistant Surgeon R. O A Smith This inquiry, led by their previous epidemiological work to suspect either the sandfly (Phlebotomus), or the minute midges Culicoides, as the transmitters of the disease, were able to show that the parasite of kala azar develops with great certainty and ease in the sandfly *P argentipes*. The investigation of the relation of these insects to kala azar transmission is now taking first place in the researches of the Commission, who have already confirmed the results of the ancillary inquiry that sandflies of the above species fed on the peripheral blood of kala azar cases, in about 25 per cent of those fed, develop infections of the mid-gut with the flagellate form of the parasite These infections by the fifth day after feeding may be so heavy as to be comparable with the condition seen in culture and in natural infections with Herpetomonas

There remains, however, much to be done before the sandfly can be stated definitely to be the transmitting agent, for the method in which the parasite re-enters man is still unknown, nor has it yet been shown by experimental feeding or otherwise that infection can result in this way Extensive investigation is also necessary even when the carrier has been demonstrated before practical results can be achieved in prevention The Commission, though now working in Assam, will undertake researches in turn or simultaneously in other provinces, in order that full advantage may be taken of comparison of the conditions in as many areas as possible It is understood that the investigation under the Royal Society will in part at least be carried out in collaboration with this Commission, thus greatly strengthening and assisting the action already taken by India for the investigation of kala azar. S. R. CHRISTOPHERS.

Series Spectra of Two-valence-Electron Systems and of Three-valence-Electron Systems.

WE have recently been able to prove that the following laws first discovered in the X-ray field, namely (1) the Moseley law, (2) the regular-doublet, or Sommerfeld, law, and (3) the irregular-doublet, or Hertz, law, hold also throughout the whole field of optics, provided only the radiating atoms under comparison have the same electronic structure but varying nuclear charge.

We have further been able to obtain in our "hot-spark" spectroscopy long series of such atoms of like electronic structure, such as the seven stripped atoms Na I, Mg II, Al III, Si IV, P V, S VI, and Cl VII, a stripped atom being defined as an atom robbed of all its valence electrons save the one that, by jumping between the series of energy levels characteristic of the atom, gives rise to the observed spectrum (Millikan and Bowen, *Physical Review*, January 1924, September 1924, April 1925).

We have also found the foregoing X-ray laws, especially the irregular doublet law, powerful means for the interpretation of complicated spectra, *i.e.*, for the picking out of the lines due to particular electronic jumps in atoms in various stages of ionisation.

We have thus recently worked out and published the fairly complete spectra of a considerable number of stripped atoms.

In the present note we present the condensed results obtained by the extension of the same method to two more series of atoms of like electronic structure, namely, two-valence-electron systems, such as Mg I, Al II, Si III, P IV, S V and Cl VI, and three-valence-electron systems such as Al I, Si II, P III, S IV, and Cl V. The method of obtaining these results will be presented in detail in forthcoming articles, but the term values divided through in each case by the square of the effective nuclear charge are presented in the following-tables, from which, however, Cl V and Cl VI are omitted because not enough lines have been identified to permit of the complete working out of term values.

Losses of Ammonia from Soil by Volatilisation.

THE present communication is a preliminary note on the subject of the loss of volatile constituents from soil, which it is proposed to investigate in detail and on a large scale in the immediate future.

It has, of course, been known for long that while the growth of grasses and tree vegetation on an undisturbed soil produces increases in the nitrogen content of the soil largely owing to the activity of a series of nitrogen fixing organisms, the cultivation of a soil in which the nitrogen equilibrium point had been raised by quiescence invariably results in a loss which was not recoverable in the crop.

In this way there is a leakage of nitrogen which represents a serious economic loss. This occurs not only in Great Britain, but is even more pronounced in those countries where climatic conditions are such as to cause a very complete desiccation and aeration of the surface layer.

It was shown by Hall and Miller (*Journal of Agric. Science*, iv. 56) that when dishes of sulphuric acid were exposed above the soil there was a small absorption of ammonia which was supposed to come from the atmosphere. They observed that very considerable quantities of ammonia were given off from the soil as a result of an application of ammonium salts, and they conclude that "if the soil is palpably giving off ammonia during the months immediately following the ammoniacal manuring it must still be doing so at other times of the year."

It has been shown previously by one of us (Oxford Forest Memoirs, No. 2) that in those soils which contain large quantities of ammoniacal nitrogen there is a considerable portion of this which can be easily removed by solution in water, and further, that when the total amount of ammonia increases during desiccation, as is normally the case, the larger part of this increase is in a form in which it can be removed by water alone.

	Moist	1st Period	2nd Period	3rd Period.
Total ammonia	11 parts per million of dry soil	16	19	22
Water Soluble Ammonia	10 „ „	13	16	19
Solubility percentage	90·9 „ „	81·25	84·2	86·38

These figures show an increase in total amount of ammonia, which is largely composed of ammonia so little retained by the soil that upwards of 80 per cent. is removed by solution in water alone. The drying of these soils was carried out slowly and without aeration.

During the desiccation the increase of ammonia did not appear to be due to denitrification, as there was an increase in the nitrate content as well during the time of drying.

	Moist	1st Period	and Period.	3rd Period.
Nitrate	49 parts per million of dry soil	53	69	69
Increase as percentage of initial concentration	..	8·2	40·8	40·8

These results and others which arose in the course of an investigation into the presence of phenols in the soil, and the observations of Hall and Miller, already quoted, led us to carry out a series of experiments in which attempts were made to aerate the soil under different temperature conditions, and to determine whether any volatilisation of ammonia could be detected

The results of the first series, carried out with dry air at room temperature, are given below. The dehydration of the soil in these took place slowly

Soil	Crop	Season	P_H	Total NH_3	Soluble NH_3	Volatile NH_3	Moisture lost during Dehydration as per cent of Dry Soil
				p p m			
Forest	Isuga	Winter	5	5 7	2 1	1 45	30
,,	Corsican Pine	Spring	4	4 95	1 5	2	35
,,	Oak	Spring	7	2 4	8	8	30
,,	Larch	Summer	4	8 8	4 8	2	41

The second series were carried out with different soils and the aeration was effected by a current of dry air, the temperature of this and of the soil being maintained above 50° C

Soil	Crop	Volatile NH_3, Parts per million of Dry Soil.	Moisture lost during Dehydration as per cent. of Dry Soil
Egypt	Cotton	1 1	15
Chalk	Barley	·5	12
Marlstone	Pasture	5	31
V rich Hothouse		1·5	62

These figures again show a considerable amount of ammonia volatilised from the soil

An apparatus is in the process of construction which will deal with large quantities of soil, and it is hoped, will enable an extended series of observations to be made with soils of different types and at different temperatures.

Robert Browning as an Exponent of Research.

I HAVE read with delight Mr Lamplugh's glowing appreciation (NATURE, February 28) of Browning's sympathy with scientific thought, and I agree with every word except that one searches vainly in "Paracelsus" for any clear appreciation of scientific research For more than forty years I have felt that that poem breathes throughout the very spirit of scientific enthusiasm which is the mainspring of research Paracelsus first "aspires"

> To contemplate undazzled some one truth,
> Its bearings and effects alone—at once
> What was a speck expands into a star,
> Asking a life to pass exploring thus

When he "attains" fame in the world he is struck with fear that his ideals may have declined with his lost youth and hopes, and exclaims

> . . . Would I were sure to win
> Some startling secret in their stead, a tincture
> Of force to flush old age with youth, or breed
> Gold, or imprison moonbeams till they change
> To opal shafts!—only that, hurling it
> Indignant back, I might convince myself
> My aims remained supreme and pure as ever!

In mature age he "aspires" again, looking back over more disappointments than triumphs, and the old passion swells up once more, struggling under the rein of reason

> And I betake myself to study again
> Till patient searchings after hidden lore
> Half wring some bright truth from its prison; my frame
> Trembles, my forehead's veins swell out, my hair
> Tingles for triumph. Slow and sure the morn
> Shall break on my pent room and dwindling lamp
> And furnace dead, and scattered earths and ores,
> When, with a failing heart and throbbing brow,
> I must review my captured truth, sum up
> Its value, trace what ends to what begins,
> Its present power with its eventual bearings,
> Latent affinities, the views it opens,
> And its full length in perfecting my scheme
> I view it sternly circumscribed, cast down
> From the high place my fond hopes yielded it,
> Proved worthless

Finally, when he "attains" to wisdom while dying in poverty and neglect, Paracelsus, "the searching and impetuous soul," reviews his career of discovery and traces the course of Nature from the time when

> The centre fire heaves underneath the Earth
> And the Earth changes like a human face,

and onward in a fine description of the origin of land, the advent of plants and animals and their development,

> Suggesting some one creature yet to make,
> Some point where all those scattered rays should meet
> Convergent in the faculties of man.

Surely this is not only appreciative but prescient also of scientific thought, for Browning wrote the poem in 1835 when Darwin was still sailing the seas, an unknown assistant-surgeon on the *Beagle*

HUGH ROBERT MILL.

The Translation of Helmholtz's Physiological Optics.

THE reviewer of Helmholtz's "Physiological Optics" (NATURE, December 20, 1924, p. 887) remarks, "at last a deep reproach has been lifted from the record of English scientific literature."

Nearly quarter of a century ago (on returning from three years' work in a German scientific institution), I proposed to Messrs Longmans that I should write a translation for them to publish They agreed, and secured the services of Sir Michael Foster to edit the work, and bring it up-to-date. Sir William Abney and other scientists warmly supported the idea. The German publishers also were quite willing, and agreed to lend their clichés. The scheme fell through because the heirs of von Helmholtz, after long delay, refused to grant the rights of translation, acting on the advice of Prof. Arthur Konig. I forget the exact terms of König's letter, but it was to the effect that the book dealt with researches which had not been completed, and therefore it would be unfair to the memory of von Helmholtz to allow it to be presented to English readers as representative of his work.

The Historical Succession of Cultural Impacts upon South Africa.

By Prof RAYMOND A. DART, University of the Witwatersrand, Johannesburg, South Africa.

SINCE their discovery by the ivory trader Adam Renders (1868) the famous Zimbabwe ruins in Rhodesia have formed the rallying-point around which a fierce and even bitter controversy has raged amongst anthropologists and others. The central point at issue is whether these stately relics owe their existence to an endogenous civilisation, which has since vanished, or to an external and highly advanced culture the impact of which, though powerful, was gradually and ingloriously diminished at a remote historical period

The conflict which has proceeded about this issue has been valuable in causing suggestive data of considerable magnitude to be placed upon record It has revealed the existence of a stupendous enterprise in mining of gold, copper, tin, and pigments which involved virtually the whole territory from the Belgian Congo on the north to the Central Transvaal on the south, and from the Kalahari Desert in the west to the Portuguese East African coast in the east. These undertakings were prosecuted with a finesse which never fails to command the respect of modern engineers Rhodesia, the centre of the mining area, is found at the present time to be pervaded by extensive monumental remains in the form of monoliths, stone circles, and stone buildings, together with vast areas of terraced cultivation In many instances the buildings reveal a nicety of architecture and a regard for sanitation such as are not characteristic of Southern African natives. Moreover, the ornamentation and objects of phallic worship found in numerous sites have betrayed to many the influence of a people with artistic feeling, and with a complicated theology and religious ritual, who were probably Phœnician, coming from Sabaea in south-eastern Arabia

Important as the information at our disposal may be, we are far from an exact knowledge in any of the fields involved in this evidence There has been as yet no systematic anthropological survey of even a portion of the territory involved In the absence of detailed and precise data, it has been easy for ill-informed argument to accumulate and the significant issues to be overwhelmed in a sea of conjecture.

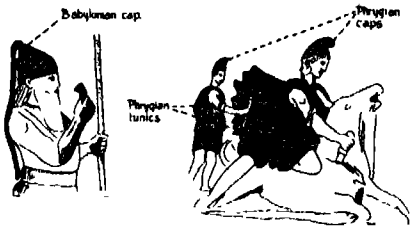
It is at this juncture that the painstaking and tireless investigations of a Trappist monk of the Marianhill Monastery in Natal appear to provide decisive information such as has been so long searched for Equipped with the knowledge of an artist skilled in reproducing and retouching medieval works of art in the Cathedrals of Cologne, Bonn, and elsewhere, Brother Otto has been copying with infinite patience for some years the Bushman paintings found in the rock shelters of the Kei River Valley, in the eastern portion of the Cape Province. Copies of certain of these he has forwarded to me with notes for the purposes of this article.

Bro. Otto is not the first investigator who has worked in this region. Stow visited a number of the caves here; and another priest, P. M. A. Schweiger, R.M.M., published (*Anthropos*, 1913) certain of the paintings which Bro. Otto has since studied more minutely. It has remained, however, for Bro. Otto to reveal the historical significance of these works of art.

In the first place, Bro. Otto believes he is able to prove that the art of painting was indigenous to this country, and was not introduced from outside. The works which illustrate the beginnings of the art are crude drawings in charcoal, chiefly of animals, and later of naked human forms revealing the well-known Bushman characteristics. Apparently, by experimenting with pigments mixed with the juices of the Euphorbia flora, works were executed with exceedingly fine brush technique The pigments, of which a considerable variety was utilised, seem finally to have been rendered impervious to the passage of time and the most rigorous climatic exposures by the discovery of the value of oil as a medium, until latterly the finest works were executed indifferently in the recesses of shelters or on the weather-beaten faces of the rocks outside

These matters are important enough, but a greater human interest attaches to the discovery that, after their technique had become perfected, the Bushman found subjects for artistic exploitation in voyagers who visited their coasts and inland rivers at a period

FIG. 1.—Bushman painting in deep red monochrome, in a cave near the confluence of Ngolosa and Kei Rivers. (After Bro. Otto.)



so remote in time that paintings depicting them are sometimes found to be partially covered by an incrustation one-sixteenth of an inch in thickness

From twenty-eight separate sites over an area twenty miles in length along the Kei River, Bro Otto has collected more than two hundred and fifty copies of painted groups, and has not omitted, to his knowledge, any detail depicted by these primeval artists within this circuit From this mine of material he is in a position to provide authoritative information concerning the homeland of these visitant navigators of early times.

A picture from a cave near the confluence of the Ngolosa and Kei Rivers in the Cape Province is represented in Fig. 1. Here we find the figures of two naked Bushmen, and of two foreigners—gigantic in the Bushman's estimation, and wearing ancient Asiatic tunics and headgear The painting depicts a scene in which a piece of clothing is about to be cast over a nude Bush maiden by a bearded man dressed in a Phrygian tunic and cap, and carrying a weapon (sword ?). Opposition is expressed in the antagonistic attitude of the naked Bushman, who carries a stick in his hand, while the operations are followed closely by the other massive figure, also clad in a tunic, but

wearing a cap of Babylonian design. This figure has no weapon, and is presumably that of a merchant captain. Other pictures of similar alien intruders show them to be usually bearded and armed with bows and arrows, shields, and other weapons—swords and javelins,—whereas the Bushman in these old pictures is generally unarmed or is armed only with a stone or a stick It seems possible from these facts that the Bushman learned the use of the bow from such visitors

It is amazing to find that the clothing and headgear

FIGS. 2 and 3.—On the left, figure of Marduk, original in the Berlin Museum (After Birkner, "Rassen und Völker.") On the right, Mithras slaying a bull, original in the Louvre, Paris (After Hochland)

of the people depicted in this painting have their counterpart upon the bas-reliefs of Babylonia and the ancient paintings and sculptures of the Mediterranean area (see Figs. 2 and 3).

It is perhaps equally remarkable that no inferences have been drawn from pictures already published similar to those in the possession of Bro. Otto. More than twenty years ago there appeared in the "Natal Railway Guide" (1903, p. 216) a picture (Fig. 4), photographed in Natal by J. E. Middlebrook, which presented the same striking juxtaposition of naked Bushmen and clothed Asiatics of the Babylonic-Phœnician period. This photograph was reproduced for the purposes of an article by D. Waterston in the *Scientific American* (1915, p. 191). In the meantime, as mentioned already, another priest, Albert Schweiger, had published (*Anthropos*, Bd. VIII., 1913) numerous pictures portraying the presence of clothed foreigners

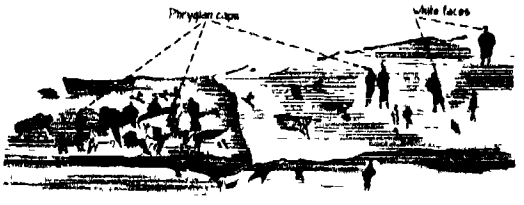


FIG. 4.—Bushman painting from Natal revealing contact of Phœnicians with Bushmen (After photograph from the "Natal Railway Guide," 1903, and *The Scientific American*)

which were gathered in the same area as that examined by Bro. Otto. A copy of one of these paintings (Tafel XI.) showing a Babylonian type of cap is shown in Fig. 5.

Pictures showing clothed foreigners are also to be found in the classical work of Miss Helen Tongue ("Bushman Paintings," Oxford, 1909). This author has published many plates of paintings copied in the eastern part of the Orange Free State and Cape Province. Plate XV., No. 102, of her work presents a "procession of men and women dressed in cloaks." The faces of the members of the procession are painted white—a feature of no small significance when it is recalled that Bushmen generally represented themselves and other African natives by means of a black or a scarlet pigment. Bro. Otto's experience agrees with that of Miss Tongue and of J. E. Middlebrook (*vide* Fig. 4) in finding the features of these alien personages depicted usually by means of a white pigment.

We have seen, then, from the independent evidence of at least four people, that foreigners who were clothed in Phœnician and even Babylonian garb were well known to the aboriginal Bushmen of the Eastern Cape Province, Orange Free State, and Natal. But perhaps the most beautiful reproduction of a Phrygian cap was discovered by Father Krauspenhaar a thousand miles north of this region, in Rhodesia, at Rusapi, which is situated on the Beira–Salisbury railway some two hundred miles inland. Fig. 6 is a drawing of Father Krauspenhaar's copy of this picture.

In a portion of the same area (Barkly East) as that examined by Miss Tongue are many pictures of clothed and capped Phœnician foreigners, some of which have been reproduced in Dr. O. Moszeik's "Malereien der Buschmänner" (Berlin, 1910, pp. 61 and 66). Barkly East is situated on a tributary of the Orange River

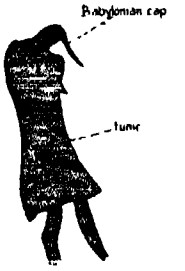

FIG. 5.—Bushman painting from "Nthintshi near Kei River, Cape Province, depicting a foreigner (Schweiger)

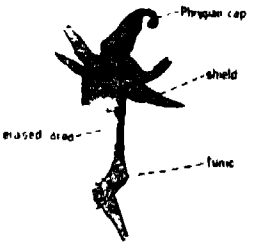

FIG. 6.—Bushman painting in monochrome red from a cave near Rusapi, Rhodesia (After P. F. Krauspenhaar.)

nearly two hundred miles inland, and consequently we are now in a position to state that the whole of the eastern portion of the African continent for some hundreds of miles inland, which lies between the latitudes of the Zambezi on the north and the Orange and Kei Rivers on the south, was exploited by the *old-colonists*, as Bro. Otto terms them, from South-west Asia in remote ancient times. He calls them *old-colonists* because he believes he is able to prove conclusively from the paintings that these very ancient voyagers not only visited these territories and carried off their denizens, particularly their women, but also intermarried with them and settled down amongst them, bringing to them novel arts and customs (Fig. 7).

The significance of these observations for the unravelling of the Zimbabwe riddle is not far to seek, for they reveal the unsound nature of Randall MacIver's theory of medieval and even Bantu origin of the ruins, mines, and agricultural terraces south of the Zambesi. The pictorial art of the Bushman has preserved through the lapse of centuries unassailable evidence of the impact of ancient civilisations of the Eastern Mediterranean and Mesopotamian areas upon a Bushman South Africa which betrayed in their day no evidence of Bantu contamination.

One of the supposedly crucial pieces of evidence

adduced by MacIver in support of his hypothesis of a medieval Rhodesia, the culture of which was of purely Bantu origin, was the constantly recurring discovery of Chinese porcelain in these ruins. The presence of this ware was rather naturally attributed to Portuguese influence. But the Chinese were navigating the Indian and Pacific oceans in luxurious fashion in the days of Marco Polo, when the Princess Kokáchin went by sea from China to Persia. Nearly three centuries before Marco Polo's time, Alberuni (about A D. 1030) records that "The reason why in particular Somanâth (in India) has become so famous is that it is a harbour for seafaring people, and a station for those who went to and fro between Sufâla in the country of the Zanj and China" (E. C. Sachau, 1910, vol. 2, p. 104) Indeed, the timid writer of the Periplus found his way south along the African coast so far as Rhapta in the first century of our era, and relates of Arab captains and agents at that period "who are familiar with the natives and intermarry with them, and who know the whole coast." There is every reason for believing that

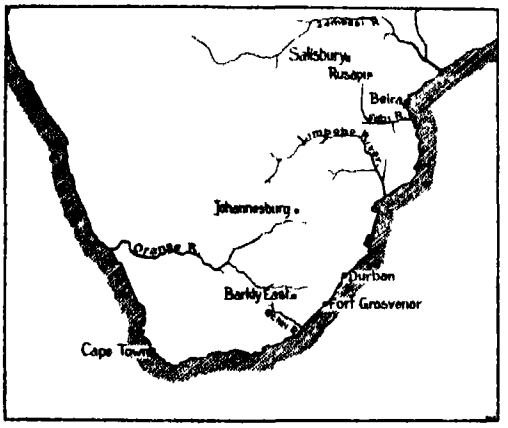

FIG. 7.

in the early centuries of the Christian era, and perhaps prior thereto, when Chinese arms were pushing far westward upon land, Chinese shipping was contesting with Indian and Arabian vessels the trade of the East African coast, which had already fallen from the hands of Egypt and Mesopotamia and those who brought and carried for these countries.

Fig. 8 is a copy of Miss Helen Tongue's Plate XVIII., No. 27, of which she states that "the whole appearance of this painting is ancient." The present interest lies in the fact that it portrays a man of light brown complexion, adorned with two necklaces, arrayed in sumptuous apparel, and carrying on his head a peaked Chinese hat. Bro. Otto has also discovered a number of pictures (*e.g.* Figs. 9 and 10) showing this unexpected type of headpiece. In the light of all these facts it must be recognised that MacIver's hastily drawn conclusions are utterly inadequate to explain the ethnological problems of the southern end of this continent.

That Rhodesia was brought into contact directly with Arabian and Indian agricultural products is shown by the fact that vines, lemons, figs, and cotton, though not indigenous to South-east Africa, are found on the terraced hills of Inyanga in Rhodesia. "Livingstone, Chapman, Burton, Kirk, and all authorities on Zambesia down to the present day have called attention to the great number of plants, fruits, and trees of Indian habitat to be found together on the Rhodesian gold-mines area. These are, of course, not indigenous to this country: the now wild *Tonge manga*, a cotton of Indian origin, not the *Tonge cadja*, which is indigenous, also a bean, *Cajanus Indicus*, known in India as the Dhal Plant, the Indian fig, grown wild; and a tree, *matuvi*, found elsewhere only in India There is also the *Mahobohobo*, which has its habitat only in Southern India and Malaya In Rhodesia this tree is only found on the area of the prehistoric rock mines, but the vast extent of the country now covered by its forests demonstrates that it arrived in some exceedingly remote time" ("Guide to Rhodesia," 1924).

Whether Chinese pottery reached Rhodesia by a European or, as is more likely, by a more direct route past India and Arabia, the discovery of it affords us little light upon what was taking place in Southern Africa long before European and even Indian and Chinese contact was possible; and it is precisely here that the evidence accumulated by Bro. Otto is of premier significance, seeing that it demonstrates an extremely ancient cultural impact upon the aboriginal Bushman

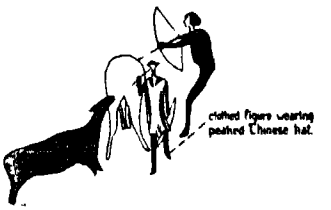

FIG. 8.—Bushman painting in light brown and dark brown, from Magdala, near Barkly East (After Miss Tongue)

FIG. 9.—Bushman painting on a stone block, Ehweni, Kei River, depicting a foreigner

FIG. 10.—Bushman painting in black from cave on the White Kei River, Cape Province, depicting a foreigner

These remarkable pictures also bring into their proper perspective a series of discoveries of a different but allied nature which have been inadequately appreciated hitherto.

About fifty years ago, Mr. Thomas Cook, who is still living in Durban, discovered twenty-eight coins in a calabash at a depth of about six feet, on the site of a native hut, near the beach at Fort Grosvenor in Eastern Pondoland. Many of these were so worn that their inscriptions were illegible—illustrating that they had been much handled—but some, which were legible, were described by Mr G. F. Hill, of the British Museum, in the *Classical Review* (of 1897 or 1898). The oldest three coins were of the period of Ptolemy I, II., and IV. respectively (*i.e.* 304–204 B.C.), and the other coins examined were Roman coins issued between the dates A.D 296 and 313, five of them being struck at Alexandria, two at Antioch in Syria, and one at Cyzicus.

This discovery is not the only one of its kind, for when the monks were building their water reservoir at Marianhill, twenty-six miles from Durban, they found, at a depth of eighteen inches in a recent stratum

of sand and humus on the side of a hill, a Hebraic coin of the reign of Simon Maccabæus (143–136 B.C.), with the inscription "fourth year of the deliverance of Sion" (*Anthropos*, Bd. V., 1909, p. 168).

Now it is conceivable that stray Egyptian, Maccabæan, Syrian, and other coins might percolate even to extreme Southern Africa without any intense cultural movement being afoot; but coins generally signify commerce, and the most cursory examination of any map of Africa south of the Zambezi will show that Palestine and Arabia—those homes of commerce—have left behind very clear evidence of a lengthy contact with this part of the globe. It is by no accident such as might conceivably determine the movement of coins, nor by any philo-Semitic proclivities of the Portuguese, that we find in Portuguese East Africa and the countries adjacent thereto place-names such as Antiocha, Jacobecua, Jacoja, Jacota, Gadsane, Gadzema, Jofane, Gaza, Gizha, Sinoia, Jobo, and the like. The two rivers Sabi and Sabie as well as Lake Sibai, together with Sabia, Sabetsi, Sebaba, Sebakwe, Shebekwe, Shibuto, Shibabara, Chabane, Chiba, Chibi, Chibambala, Chibababa, and so on, owe their names to a people fascinated by the central root Saba, Seba, or Sheba, just as the Dutch have left in South Africa their "fonteins" and "burgs," the English their "Londons" and "Cambridges," and the Scotch their "Dundees" and "Glencoes". So, too, Masibi, Mazibi, Mazibila, Masipe, Mripa, Mriba, and Mareba have an intimate relation with Marib, in the same way as Mocuba, Mokuba, Mkubi, Namoko, Makiki, Muchacha, Machiche, and Machacane recall the Arabian Mocha.

In brief, the themes for the variations provided by hundreds of place-names south of the Zambezi lie in the Asiatic continent, and still await the investigations of specialists in this field. The evidence to be culled from this study will be especially valuable in "dating" and "placing" the different cultural intrusions. Many of the Arabian names are undoubtedly pre-Koranic. In addition to names from Western Asia, there are Indian types such as Ricatla, Mandle, and Kande, and variants of the old name of Japan (Zipangu), namely, Chipanga and Chipinga. I have entered into this matter of place-names in some detail because, rich as the field obviously is, I am not aware of any serious study of this sort made hitherto upon this locality.

FIG. 11.—Bushman painting from "Ngolosa" (Kei River), revealing Egyptian characters in clothing and head dress. (After Schweiger.)

We have considered already evidence which indicates that, prior to the coming of the European, not only mediæval Arabian, but also Indian, Chinese, pre-Koranic Arabian (Himyaritic-Sabaean), Palestinian, Phrygian, and even Babylonian influences have played a part in moulding the destinies of the primitive peoples of Southern Africa. There are not lacking evidences that Egypt, too, was in intimate contact with this remote region. There is one picture of Schweiger's from the Kei River Valley (Fig. 11), in which the head-dress, clothing, and artistic feeling is positively Egyptian. However, I would have disregarded this picture if I had not been arrested while in Marianhill by the persistence of the same Egyptian fashions of head-dress amongst the native women at the present day. The photograph reproduced in Fig. 12 reveals Egyptian characters not only in the head-dress

FIG. 12.—Native women, Marianhill, Natal, showing Egyptian characters in head dress and clothing.

and the head-ring, but also in the clothing (suspension at the waist, fringe at the lower margin), and even in the features of one woman; the other looks Semitic, but neither is frankly Negroid or Bushmanoid. For comparison with Figs. 11 and 12, I have reproduced one of the figures in the procession of servants of the Queen Hatshepsu who visited the Land of Punt (Fig. 13).

FIG. 13.—Figure in procession of Queen Hatshepsu's servants, to illustrate Egyptian head-dress and clothing.

In this connexion, it will be recalled that Dr Karl Peters discovered (Keane's "Gold of Ophir") in Rhodesia a figurino of an Egyptian courtier—of the period of Thothmes III. (Dynasty XVIII.)—holding in his hands the scourge of a slave-driver. Further, most authorities concur in believing that the steatopygous Queen of Punt and her daughter portrayed in the spoils of the voyage of the sister of Thothmes III., Queen Hatshepsu's (1501–1479 B.C.) servants to the divine South-land, was a Bushwoman or closely related to one. Thus Sir Flinders Petrie ("History of Egypt," vol. 2, 1899) says, "The strange fatness of the queen has been much speculated upon; whether it was a disease such as elephantiasis, or was natural fat, has been debated; but as her daughter shows much the same tendency of

curve in the back, it is probably the effect of extreme fat, which was considered a beauty, as in South Africa at present." Rawlinson (*Ancient Egypt*, 1893) is still more emphatic when he states, "She belonged, more probably, to one of the dwarfish tribes of which Africa has so many, as Dokos, Bosjesmen, and others."

The land of Punt is generally supposed to have been south-eastern Arabia or some point along the southern Somali coast; the spices, resins, and incense products being in favour of the former; the giraffes, ivory, cynocephalous apes, and the like speaking for the latter. Frobenius ("Das unbekannte Afrika," 1923) has shown in a map the distribution of houses on piles such as were seen by these voyagers to Punt. None such are to be found in Arabia or Somaliland, but they are found on the big rivers of Africa southward from Somaliland. Resins and snuffs have the highest of values amongst the Bush people even in modern times I do not say that the data are conclusive to prove that God's land, Punt, lay in Africa south of the Zambezi, but the facts are highly suggestive The products of the country--people, animals, gold, resins, pigments, and the like--were such as this country certainly was affording in plenty at that remote period At the same time, it is a well-recognised fact that for centuries, perhaps millennia, prior to Queen Hatshepsu, ships had been navigating the Red Sea, the open ocean, and the Persian Gulf between Egypt and Mesopotamia. It is not reasonable then to imagine that the Egyptian queen would render herself a laughing-stock before the civilised world by celebrating in the building and decoration of a new temple as extravagant marvels the products of places near by like the coasts of Arabia and Ethiopia. To fit out an expedition for this remote South-land of Punt was always an epochal event, and was carried out only by the greater Pharaohs in times of peace and prosperity, and was even then worthy of record. Such expeditions are recounted in the times of Sankh-ka-ra (Dynasty XI.) under the nobleman Hannu, of Hatshepsu, of Thothmes III.—the Napoleon of Egyptian history—and of Horemheb (all three of Dynasty XVIII.), and of Rameses III. (Dynasty XX.). It is absurd to believe that these proud names in Egyptian history would reckon trips to little beyond the mouth of the Red Sea as worthy of mention when the equipment of voyages three years in duration were commonplaces in the chronicles of the pigmy court of Solomon. Even in the humdrum days of Herodotus, one circumnavigation of Africa had not been entirely forgotten, for he relates how King Necho's Phœnician servants had accomplished this hardy feat.

His Honour the Administrator of the Transvaal (Prof. Jan H. Hofmeyr) has informed me that the remains of what was presumably an ancient galley were discovered during the laying out of the Maitland Cemetery on the Woltemade flats near Cape Town in the 'nineties. At that time the contact of one end of Africa with the other by navigation was undreamt of, and the significance of finding a boat, one hundred and eighty feet in length, buried six feet underground at a distance of three miles from the present coast-line, was lost on the workmen, who utilised it for firewood The event at least indicates that the followers of Prince Henry were not the first to anchor in Table Bay

The continuity of the Atlantic and Indian Oceans around the southern extremity of Africa was customarily portrayed by the ancient cartographers of Greece (*e.g.* Globe of Crates), of Arabia (*e.g* Idrisi), and of Europe from Venice to Anglo-Saxon England (*vide* "Encycl Britt.") It is difficult to understand how such conceptions could have grown up and persisted in this fashion unless the experiences of ancient voyagers had provided some foundation for them. It is likely that the voyage of Necho's servants was but a repetition of many similar ventures in the storied past In any case the tale provided by Herodotus is more easily believed when we know that Bushmen from the Zambezi to the south-eastern corner of the continent on the shore-coast and for hundreds of miles inland have recorded in portrait the arrivals and the activities of not merely one but untold numbers of invaders at successive historical epochs.

It is not in the contact of any one people but in the endless procession of emissaries of every great navigating power in the Indian Ocean down this coast that one finds an explanation of the prodigious extent of the early mining industry of Southern Africa. Moreover, it is only in terms of this procession that the physical, anthropological, and ethnological problems of this country can be adequately understood. It is impossible here to do more than direct attention to certain aspects of these intricate but highly fascinating studies. It has already been stated that no exhaustive anthropological survey of the region concerned has been made; but if the urgent necessity for such a survey of the paintings, ruins, terraces and mines, and the nature and richness of its prospective fruits, are indicated, these meagre notes will have been justified.

Biographical Byways.[1]

By Sir ARTHUR SCHUSTER, F.R.S.

12. ESMATT EFFENDI.

I AM not aware that any publication of Esmatt Effendi has ever seen the light of day, but nevertheless my readers, I hope, will agree that his name deserves to be included in this collection of reminiscences. He certainly possessed two essential qualities, enthusiasm and perseverance. I made his acquaintance at Suez, on the evening of May 3, 1882, when, on behalf of the Khedive of Egypt, he received a party sent out under the auspices of the Royal Society to observe the total eclipse of the sun that was to take place on May 17 at Sohag, some way up the Nile. He gave us a very promising account of the local facilities, more especially with regard to bricks and mortar for the foundations on which to place our telescopes; and if his predictions did not come true, and the only brick we saw was that aimed at the head of one of the party by an inhabitant of the village, his intentions were undoubtedly good

Esmatt Effendi had an ambition to learn something about astronomy, and showed great interest in a

[1] Continued from p. 385.

sextant that I had taken out to check our chronometers. He begged me to teach him its use. After a few lessons, I found him one day trying to find the image of the sun in an artificial horizon, having pushed all dark glasses out of the way. I had warned him against this, and got rather angry with him He replied, "I am an Egyptian, and I cannot see the sun with the dark glasses. When an Egyptian says he is going to do something he is going to do it, and I am going to see the sun through this sextant even if I lose my eyesight" I had to lock up the sextant

It was some years before I heard of Esmatt again. Through diplomatic influence, the Naval Observatory at Washington had been persuaded to take him in as a kind of apprentice They found him, as I had done, persevering and enthusiastic, but incapable of assimilating any knowledge They tried to persuade him to return home and take up some other occupation, but Esmatt Effendi had made up his mind to stay The authorities of the Observatory learned afterwards that all the time he was half starved, and had to sell his books and a great part of his clothing to pay for his board and lodging Matters ultimately reached a crisis and he was told to leave He finally consented, on condition that the authorities would give him a testimonial which would enable him to find a position at home They considered the matter, and ultimately resolved that it was worth while to stretch a point, and they sent him the requested testimonial To their surprise, they found Esmatt again at his desk next morning. He was reminded that they had kept their part of the bargain and that he must keep his. Esmatt stood up, took the testimonial out of his pocket, waved it in front of their faces, and said, "The man who deserves this testimonial deserves to work in the Observatory of Washington." The rest of this story, which I give on the authority of one of the principal astronomers concerned, must be left to the imagination.

Conclusion.

It is with some hesitation that I conclude these reminiscences with the account of an incident that revives painful recollections, and the publication of which I should, for obvious reasons, have preferred to be left over until after my death It concerns a distinguished personality whose memory is cherished by many friends, but their ranks are now rapidly thinning, and for this reason I feel compelled to disregard personal considerations.

Early on during the War, I was one morning surprised to find paragraphs in the daily press implying that a wireless apparatus had been found and "seized" in my house, with more or less veiled references to the purpose for which the apparatus was likely to have been erected. The complete story may be told some day; at present it is sufficient to say that I do not blame the newspapers

Though I knew that the implied accusation was not likely to impress my friends, the matter, in view of my position at the time, was serious, and it was with fear and trembling that I entered the Athenæum a few days later and selected a solitary place in the coffee-room. I was leaving again directly after luncheon, and as I was putting on my coat in the hall I suddenly felt some one stepping up behind to help me. Surprised at this politeness, which is somewhat unusual in the Club, I turned round and looked into the kindly face of Lord Roberts, with whom I had no personal acquaintance The hall was then full of members of the Club, and it was obvious that the action was intended to be, and in fact was, a demonstration. Such incidents are not likely to be forgotten.

Obituary.

Prof. W. A Haswell, F.R.S.

THROUGH the death of Prof. W. A. Haswell, at the age of seventy-one, zoology has lost one of its foremost exponents, and the University of Sydney a teacher and investigator of world-wide reputation.

William Aitcheson Haswell was born in Edinburgh in 1854, and was educated at the Edinburgh Institution and the University, where he gained the Bell-Baxter Scholarship as the most distinguished natural science graduate of his year. As quite a young man he went out to Australia and, settling down in Sydney, there spent the rest of his life. In 1880 he held the post of curator of the Queensland Museum. Then, returning to Sydney, he delivered public lectures on zoology, and became in 1882 acting curator of the Australian Museum, and published his valuable Catalogue of the Australian sessile- and stalk-eyed Crustacea. In the same year he was appointed lecturer in zoology and comparative anatomy in the University of Sydney, under Prof W J Stephens, who at that time held the chair of natural history. Young and enthusiastic, Haswell threw himself with great energy into the study of the rich fauna of Port Jackson and the adjacent coasts, and in the course of a few years published, in the Proceedings of the Linnean Society of New South Wales, numerous papers, mainly of a systematic character, on the Crustacea, Annelida, and Bryozoa of the Australian seas In particular we owe to Haswell the first description, in 1882, of the giant Phoronis that occurs in Port Jackson, which he named *Ph. australis*, and in the same year he exhibited drawings of the early stages of its development before the Linnean Society.

During this period, however, Haswell by no means confined himself to invertebrate zoology, but contributed to the Linnean Society valuable papers on vertebrate morphology, on such diverse subjects as the anatomy of birds, the structure of the paired fins of Ceratodus, the skeleton of elasmobranch fishes, and the early stages of the development of the emu (1887). He also described in 1886 in the *Q.J.M.S.* the remarkable striate muscle fibres in the "gizzard" of the polychæte worm Syllis, and in 1889 published a very interesting comparative study of the same fibres. In 1888, also in the *Q.J.M.S.*, he gave the first detailed account of the anatomy of that remarkable ectoparasitic trematode, Temnocephala, a form which will always be associated with his name.

Such was the reputation Haswell had established for himself as an original investigator and teacher that the Senate of the University of Sydney, when the

Challis professorship of biology was instituted in 1889, appointed him to the chair, without advertisement—at the time a most unusual proceeding—and this he held continuously until his retirement in 1917. All through these years his scientific activity continued unabated.

In 1893 Haswell published, in the Macleay Memorial Volume, his great monograph on the Temnocephaleæ, a group which occupied his attention right up to the end of his working days, for the last paper he wrote is entitled "Critical Notes on the Temnocephaloidea," and was published in the Proc. Linn. Soc. N.S.W. so recently as December 29, 1924. In the volume above mentioned he also described the remarkable new type, Actinodactylella, from the gill-cavities of the Gippsland burrowing crayfish, *Engæus fossor* In numerous papers, published mainly in the *Q J M.S* and the Proc. Linn. Soc N S W., he contributed largely to our knowledge of the Turbellaria, both fresh-water and marine, and the Cestoda, and by his discovery of the histriobdellid, Stratiodrilus, and his detailed accounts of its anatomy and development, he greatly extended our knowledge of the "Archi-annelida," whilst to him we are indebted for the only available account of the early development of the Port Jackson shark (Heterodontus).

Outside the ranks of professional zoologists, Haswell is perhaps best known to the scientific world as the joint-author, with his staunch friend the late Prof. T. Jeffrey Parker, of the monumental "Text-book of Zoology," which, issued in 1898, is now in its second edition and is accepted as a standard text-book in zoological laboratories all over the English-speaking world.

Amidst all his academic work Haswell found time to take an active interest in the various Australian scientific organisations He was for long on the Council of the Linnean Society of N.S.W, and acted as its president in 1892–93; he was president of Section D of the Australasian Association for the Advancement of Science in 1891, and he was for many years a trustee of the Australian Museum. In 1916 he edited the Reports of the Australasian Antarctic Expedition

Haswell was a man of wide knowledge and culture. Shy and somewhat reserved in disposition, he was a loyal, warm-hearted, and ever helpful friend and a kindly and charming host. He was a keen trout-fisher, enjoyed a game of golf, and was an ardent gardener. In 1894 he married Josephine Gorden Rich, a pupil of Jeffrey Parker and joint-author with him of a paper on the myology of Palinurus, and she always took a lively interest in her husband's work. She and an only daughter survive him.

Haswell was elected a fellow of the Royal Society in 1897, and was a member of numerous societies both at home and abroad.

The writer will ever bear his old chief in grateful memory for the forbearance and many kindnesses he showed him during an association of some fourteen years. J. P. H.

PROF. JOHN CLELAND, F.R.S.

PROF. JOHN CLELAND, who died on March 5, in his ninetieth year, held the chair of anatomy in Queen's College, Galway, from 1863 until 1877. In the latter year he succeeded Dr. Allen Thomson as occupant of the chair of anatomy in the University of Glasgow, which he held until 1909, retiring at the age of seventy-four to spend the happy evening of his days at Crewkerne, Somerset.

Cleland was a man of imposing appearance who impressed on the generations of students who passed through his class-rooms his love of knowledge, his wide culture, and independence of outlook He was beloved by his students. All his life long he was fighting a rear-guard action. He was born and bred in pre-Darwinian days and grew up in the school represented by John Goodsir and Richard Owen He believed in evolution—particularly the brand represented in the "Vestiges of Creation." He could not abide the dogmatic assurance with which Huxley proceeded to sweep the "underlying element of spirit" from all biological processes For him Darwin's law of "Natural Selection" was true and potent, but in his opinion this law was powerless in the production of purposive adaptations He was a student of "morphological design" and believed that a "unity of cause" worked through "the ordered sequence to be seen in all biological events." The "morphological beauty of the skull" was almost one of his religious tenets Those who know the researches and writings of John Goodsir will realise how strong was the influence which the master exerted on John Cleland seventy years ago. With him goes the last representative of the transcendental and philosophical anatomists of the nineteenth century.

Cleland was born in Perth in 1835, the son of a medical man He was turned from the Church to medicine by his mother, and began his studies in the University of Edinburgh in 1852. Goodsir, then a man of thirty-eight, was at the height of his fame and immersed in researches of the most diverse kinds, but was particularly enamoured of Owen's speculations regarding the "original design" which was supposed to underlie the head and body segments of vertebrate animals When Cleland became junior demonstrator to John Goodsir in 1857—Sir William Turner was then senior demonstrator– he applied himself chiefly to the morphological problems of the vertebræ and of the skull He published many dissections made on rarer animals, but the work he will be best remembered by is that done on the human skull Unfortunately, in 1857, Goodsir's great gifts were already being sapped by the disorder which carried him off ten years later; it is vain to speculate now as to the course events would have followed if Goodsir had retained his full powers of mind; his disease certainly fanned his tendency towards transcendentalism, and it was this side of his mind which had the strongest influence on his junior demonstrator.

In 1861 Cleland left Edinburgh to demonstrate anatomy under Prof. Allen Thomson of the University of Glasgow, one who was a master of scientific method. In 1863 he was appointed to his first chair, in Queen's College, Galway. His best known research was done while he was there, and was published in the Philosophical Transactions (1870, vol. 160, p. 117), on "An Enquiry into the Variations of the Human Skull, particularly in the Antero-posterior Direction." This inquiry has not received the attention it deserves, for in

it Cleland directed attention to the remarkable changes in shape which the human skull passes through at various stages of growth of the child and at later phases of life. Even in adult years head form is not fixed; significant changes may occur in the later decades of life. Between 1855 and 1906 he published more than fifty separate papers and covered a variety of subjects. He was a poet and published a book of verse, "Scala Naturae" (1887); a volume of essays, "Evolution, Expression, and Sensation" (1881); he was one of the editors of the seventh edition of Quain's "Anatomy" (1867), with his former pupil, now Principal J. Yule Mackay of University College, Dundee, he wrote a text-book on "Anatomy (Human Anatomy, General and Descriptive)," 1896, and a "Directory for the Dissection of the Human Body" (1877). A. K.

Dr A de Watteville

Dr de Watteville, whose death, at the age of seventy-eight, occurred in Switzerland on February 24 last, was a prominent member of the medical profession in London between twenty and thirty years ago. A Swiss by birth, scion of one of the oldest families of Switzerland, he was an Englishman by education, and qualified for the medical profession. He specialised in neurology, and more particularly in electro-therapeutics, which he did much to establish on a scientific basis. His work on "Medical Electricity," which ran through two editions—the second in 1884—established his reputation as the chief authority on the subject in Great Britain. He specially insisted on measurements of current strength as the essential condition of a rational application of electricity, and led to the milliampere being adopted as the electro-therapeutic unit by the International Congress of Electricians.

It was, however, as editor of *Brain* that Dr de Watteville found his chief interest and occupation. In 1883 he became associated as co-editor with the original founders and editors of this important journal—the late Sir J. C. Bucknill, Dr. Hughlings Jackson, Sir J. Crichton-Browne, and Sir David Ferrier—and in 1886 was appointed sole editor, when *Brain* became the official journal of the newly founded Neurological Society. This post he held until 1900. On his resignation the council of the Neurological Society by unanimous resolution paid him the following well-merited tribute:

The Council accepts with great regret Dr. de Watteville's resignation of the Editorship of *Brain*, and desires to take this opportunity of recording the deep debt of gratitude that the Society owes him for the way in which he has conducted the Journal for the past twenty years. The Council feels that parting with Dr de Watteville is an event of great moment to the Society, for he has not only brought *Brain* to a high standard of perfection and secured for it a great European reputation, but even the existence of the Journal at the present time is due to his energetic action at a critical juncture in 1880. Moreover, the Council is mindful that the Society itself took origin on Dr de Watteville's initiative at a meeting held at his house on November 14, 1885.

Soon after resigning the editorship of *Brain*, Dr. de Watteville left London and went to reside in Switzerland, and spent the remainder of his life in quiet study and contemplation among the beautiful surroundings of his native land. Dr de Watteville was a man of wide culture and great force of character, charitable and self-sacrificing almost to a fault, and the outspoken foe of quackery and pretence of every description. D. F.

We regret to announce the following deaths:

Dr. W. F. Hillebrand, chief chemist of the U.S. Bureau of Standards, who was distinguished for his work on rock and mineral analysis, on February 7, aged seventy-one.

Prof. A. von Wassermann, emeritus professor of experimental therapy and immunology in the University of Berlin and director of the Kaiser Wilhelm Institute for Experimental Therapy in Berlin-Dahlem, on March 16, aged fifty-nine.

Current Topics and Events.

Elsewhere in this issue is an article by Prof. Raymond Dart dealing with certain evidence which, on his view, reveals a long history of cultural contact between South Africa and the outside world from an early date. It is scarcely necessary to emphasise the importance of Prof. Dart's views in relation to the "diffusionist" theories which have been put forward by Prof. Elliot Smith and his colleagues. Perhaps the most striking piece of evidence with which Prof. Dart deals is the parallel drawn between the head-dress and clothing of certain figures in the Bushmen paintings of the Kei River Valley and of figures in the art of Babylonia and Western Asia. Bushmen paintings are thought by some, for good reason, to be relatively modern, the evidence of the incrustation of which Prof. Dart speaks is of little value without further information as to its character and rate of deposit. If the identification of the Babylonian cap were accepted, it would suggest the eighth century B.C. as a probable date, but without a strong corroborative evidence the identification is precarious, especially as this type of cap is of extreme rarity in Babylonian art. Prof. Dart is on surer ground when he points to the problem presented by the extensive traces of early mining activity in Rhodesia. It may be that the researches of the Committee of the British Association which is investigating the composition of early bronzes may point to South Africa as one of the possible sources of supply and thus afford some clue to the date of some of these workings. It is, however, beyond question that the discovery by Dr. Randall-MacIver in the ruined structures of Rhodesia of Nankin china which could not be dated at the earliest much before the fourteenth century, is a great stumbling-block in the way of those who seek to prove an early date for the Zimbabwe culture.

With the past two or three weeks reports have reached Great Britain of a new experiment carried

out by Prof Michelson and Dr. Silberstein in the United States, on the principle of the Michelson-Morley experiment, to test the drift of the ether in relation to matter in motion. No authenticated account of the experiment is yet available, but references have been made to it in letters from the United States, and the *Morning Post* of March 2 and 7 published articles stating that evidence of relative motion of ether had been obtained. It is stated that a triangle of three water conduit pipes was used, and that the velocity of light travelling round the triangle was found to be different in two opposite directions Sir Oliver Lodge, in reply to an inquiry as to whether he had received any details of the experiment and the result, has been good enough to favour us with the following comments upon the subject: "In response to your inquiry, and judging solely from the newspaper accounts, the experiment mentioned as having been conducted by Prof Michelson and Dr Silberstein appears to be a repetition of the Fizean moving-water experiment, in which the water is this time kept stationary with respect to the earth, and only shares the earth's rotation. If the rest of the apparatus did not share the earth's rotation, no one would doubt a perfectly calculable positive result. The difficulty and interest arise from the obvious fact that the rest of the apparatus must have shared in the earth's rotation; so that an effect was (presumably) observed which did not involve relative motion of matter. But, assuming all this true, the obvious way out is that 'rotation' has always been regarded as exceptional; and the observation, however interesting and important, need be no more perturbing than Newton's bucket or the shape of the earth"

AN important discovery by the Harvard-Boston Expedition to Egypt, which is working among the Giza pyramids, is announced According to a *communiqué* issued by the Egyptian Ministry of Public Works which appeared in the *Times* of March 10, a tomb has been found of which the burial chamber is at the bottom of a 150 ft. shaft Although no detailed examination had then been possible owing to the unsafe condition of the shaft, a rectangular alabaster coffin was visible with a number of poles, the tops of which were covered with gold foil. Among inscriptions on a plank by the side of the coffin was the cartouche of Seneferu, first king of the Fourth Dynasty, which would suggest that it is the burial-place of a member of his family. The unusual depth of the shaft, however, and the fact that it is filled with concrete and cement instead of rubble as in other tombs in this area, have been taken to support the view that this is the tomb not merely of a personage of importance—a high official or a member of the Royal Family—but possibly of King Seneferu himself, although he is usually supposed to have been buried at Medum, where he built a pyramid. Dr. Reisner, however, who is in the United States, has cabled since the announcement of the discovery that the tomb is that of the Princess Medti-Seneferu. Presumably he has definite evidence to this effect. The floor of the tomb is covered by a quantity of objects, including alabaster bowls, a copper basin or ewer, and remains of heavily gilded chairs If it should appear eventually that this is the tomb of the King himself, it would constitute a discovery of great historical importance, but scarcely of less moment to the archæologist is the evidence which the tomb will afford in regard to the art and technique of the smaller objects mentioned, of which at this period little is known.

THE sixth of Sir Oliver Lodge's series of "talks" on "Ether and Reality," broadcasted from the London station (2LO) of the British Broadcasting Company on Tuesday March 17, dealt with matter as one of the forms of energy. Sir Oliver said that one of the functions of the ether is the constitution of matter itself Atoms are built of electrons and protons, and electrons are evidently composed of ether, because whatever mass they have is represented by the energy of their electric field, though we cannot yet, with any certainty, make a similar statement about a proton We know, however, that both are more massive when moving than when they are at rest Their mass and energy increase together, the extra mass behaving like additional matter, but not like permanent matter When an electron is stopped, the additional matter disappears. it is changed into radiation and travels out as a quantum with the speed of light There is a curious kind of discontinuity in the immediate neighbourhood of a material nucleus: the satellites can occupy certain positions and no others But they can drop from one of these positions to another, and they then emit energy in the form of radiation, which depends on how far they have dropped and where they drop to. The process is a reversible one, and when radiation is absorbed, the electron is jerked up again How far it is jerked up depends on the kind of radiation. The important thing is that matter is turning out to be one of the forms of energy This has been proved for temporary matter, and is probably true for permanent matter also, a conversion of which is believed to account for stellar radiation Whether the process is reciprocal—whether radiation can ever generate not only temporary matter but so-called permanent matter—still remains to be discovered

A SCHOOLBOY once replied to the question "What is an egg?" by stating that an egg is "an oval-shaped article of diet." The Concise Oxford Dictionary says that it is a "spheroidal body produced by female of birds, etc., especially of domestic fowl, containing germ of a new individual" Neither of these definitions can be regarded as entirely satisfactory from the scientific point of view, but the latter has the advantage of grasping to some extent the fundamental point and of restricting the application of the term to bodies of a similar nature A more precise definition is usually given by biologists of the Latin word "ovum," used as a technical term; an ovum, or egg-cell, is a nucleated cell capable of developing (usually after union with a spermatozoon) into a new individual; a conception, of course, that was as unfamiliar to Latin writers as it still is to dealers in eggs. An embryo, on the other hand, is an individual in an

early stage of its development from the ovum. Unfortunately even men of science still use these terms in a very unscientific manner Human embryologists not infrequently apply the term "ovum" to quite advanced embryos, thus counteracting the efforts of those biologists who wish to emphasise the fundamental fact that every typical animal starts life as a single nucleated cell—to which alone the term "ovum" should be applied

IN their interesting and beautifully illustrated paper on "The Early Development of the Cat" (*Quarterly Journal of Microscopical Science*, vol. 68, Part IV), Prof. J P Hill and Dr. Margaret Tribe use the word "egg" in much the same way, but what justification can there be for this usage? It fulfils the requirements neither of popular language nor of scientific terminology. It is perhaps less objectionable than the illegitimate use of the word "ovum," which is evidently intended as a technical term and therefore ought to be used only with scientific precision But in what possible sense of the word are these early embryos of the cat eggs? They are not articles of diet, and they are in no way comparable to the egg of a fowl, but only to something which may, in certain circumstances, be found in the egg of a fowl. We call this something an embryo—why should not the same term be used for the early stages in the development of the cat? It is in no mere carping spirit that we venture to make these criticisms, but with the view of directing attention to the necessity for a more rational system of terminology in embryological writings, and nothing that we have said must be regarded as indicating any want of appreciation of a most careful and accurate piece of work, a notable contribution to embryological science

A TIDE predictor has been presented to the Tidal Institute at Liverpool and has been installed at Bidston Observatory The machine has 10 semi-diurnal components, 6 diurnal, 3 third-diurnal, 4 quarter-diurnal, and 3 sixth-diurnal components, 26 in all, provision has been made for the addition of other components, if desired Long-period components have been omitted, as such constituents are easily allowed for, if of importance Very great care has been given to matters of design and workmanship, and the machine has been constructed in an admirably efficient manner by Messrs Kelvin, Bottomley and Baird, of Glasgow The accuracy of performance of the machine is very great, and it is capable of being used even for research work A noteworthy feature of the machine is the provision of apparatus for recording electrically the time at which the tide reaches a definite height The electrical contact is made by a roller on the edge of a wheel, which is attached by a flexible wire to the pen, and the electrical circuit is completed through a dotting apparatus which registers on a revolving drum. The dots are arranged on a spiral line. This chronograph can be used for registering the exact time of high (or low) water by setting on the machine the desired harmonic constants representing the rate of rise and fall of tide. The donors of the machine are Messrs. Alfred Holt, the Booth, Cunard and Orient S.S Cos, Mr. Harrison Hughes, Mr. C. Livingston, and the Local Committee for the Liverpool meeting (1923) of the British Association.

THE *Welsh Journal of Agriculture*, of which the first number has recently been issued, is intended to fill a definite need by providing a channel whereby farmers and others in the Principality can be kept informed of the progress of agricultural education and research in Wales. The published articles are to be based on scientific investigations, and will convey scientific and technical information set out in plain language to render it of the greatest possible value to the agricultural community. The first number appropriately leads off with an outline of the history of agriculture in Wales, by C. Bryner Jones, followed by an article on the human side of the farming business by A W Ashby. Other articles of a general character, but all having a bearing on agricultural development, are given, dealing with genetics and the stock breeder, modern tendencies in soil research, and with various aspects of research in such fundamental matters as animal breeding, dairying, horticulture, and fruit culture The rest of the volume is occupied by a number of short papers on various Welsh investigations and by an important article by Prof Stapledon on "Seeds Mixtures for Temporary Grass" This outlines the results of investigations carried out in Denmark and Sweden in comparison with observations on similar trials now in progress at Aberystwyth, and is of much value as a contribution to the perennial problem which confronts the farmer who desires to put down leys of long or short duration A useful list of recently published agricultural books is included, together with a section of abstracts, reviews, and bibliographical notes.

SIR E JOHN RUSSELL, Director of the Rothamsted Experimental Station, Harpenden, Herts., has been elected a corresponding member of the Paris Academy of Sciences, in the Section of Rural Economy, in succession to Prof. Winogradsky, who has been elected a foreign associate

THE Summer Time Bill was read a second time in the House of Commons on March 13. By it the dates between which legal or clock time is to be one hour in advance of Greenwich Mean Time are from the Sunday following the first Saturday in April to the Sunday following the first Saturday in October. If the measure is passed, summer time will begin this year on April 5 and end on October 4. The period during which legal time is thus to be advanced has been decided upon in agreement with France and Belgium, and is to be the same every year instead of being determined year by year, as has been the case since summer time was first introduced in 1916.

ON Tuesday next, March 24, at 5.15, Prof. A. S. Eddington will begin a course of two lectures at the Royal Institution on the internal constitution of the stars; on Thursday, March 26, at the same hour, Mr. T. Thorne Baker will deliver the first of two lectures on the chemical and physical effects of light:

(i.) "Reproduction of Light Images by Photography," (ii.) "Transmission of Light Images by Electricity"; and on Saturday, March 28, at 3 o'clock, Prof J. H. Ashworth commences a course of two lectures on the nervous system and some reactions The Friday evening discourse on March 27 will be delivered by Sir Ernest Rutherford on "Studies of Atomic Nuclei," and on April 3 by Sir Daniel Hall on "The Productivity of English Land"

THREE research assistants are required at the Building Research Station of the Department of Scientific and Industrial Research. Candidates must be honours graduates in chemistry or have an equivalent qualification, with some experience in research One post requires a special theoretical knowledge of paints and varnishes, another of physical chemistry, and another of inorganic chemistry, a good knowledge of metallography, and ability to read French and German Applications, upon a special form, must be received by, at latest, March 28 by the Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S W.1

AT the annual general meeting of the Ray Society on March 12, the following officers were re-elected: *President*, Prof. W. C M'Intosh, *Treasurer*, Sir Sidney F Harmer, *Secretary*, Dr W T Calman Lord Rothschild was elected a vice-president, and Prof A. E Boycott and Mr R T Gunther were elected new members of council It was announced that the first volume of "British Hydracarina," by Mr C D Soar and Mr W Williamson, would shortly be published, and that the issue for 1925 would be the "Life of Wilhelm Hofmeister," by K v Goebel, translated by Prof. F O Bower The Society published in 1862 a translation of Hofmeister's work on "The Higher Cryptogamia," and it seems fitting that the life of the author should now be included in the same series. The Council has also undertaken to publish a monograph on "British Sea Anemones," by Mr. T. A. Stephenson, which will be illustrated with coloured plates from drawings by the author It is intended that the first volume shall form the issue for 1927.

WE learn from *Science* that it has been decided to establish a National Hall of Fame for Engineers, Inventors, and Industrialists in the proposed National Museum of Engineering and Industry to be erected in Washington. Records of the achievements of the outstanding leaders in invention and engineering, now scattered throughout the country, are to be assembled, and all original models, so far as recoverable, are to be obtained for the museum. In addition to the central museum, it is hoped to form a chain of local museums of industry in the industrial centres of the country. Among those who probably will be represented in marble or in bronze in the Hall of Fame will be Charles P. Steinmetz, Alexander Graham Bell, Thomas A. Edison, Orville and Wilbur Wright, Eli Whitney, Captain John Erikson, Mergenthaler, and Robert Fulton.

THE report of the Department of Agriculture of the Tanganyika Territory for the year ending March 31, 1924, gives an account of attempts to improve and extend crop production in that region of Africa. Among the most important features of these experiments was the introduction of ploughing among native cultivators The sub-district of Shinyanga was selected for the experiment as having certain advantages in a closely settled population and extensive areas of cultivable soil in open country free from the tsetse fly. The attempt was facilitated by the growing interest of the natives in cotton production, while the tribal organisation lent itself readily to a system of cultivation by communities A station for the training of oxen was established, where the natives were instructed in ploughing Twenty-five ploughs were then issued to native villages, with the result that 500 acres of land were put under cotton, and requests have been made for a supply of 320 additional ploughs for use during next cotton season A further development of the work which is even more striking consists in the extension of ploughing into areas at present covered by bush and infested by tsetse fly This not merely increases the area available for cultivation but also causes the recession of the fly-stricken bush, which was advancing into open country and restricting cattle-grazing grounds

THE Botanical Society and Exchange Club of the British Isles issues with its report for 1923 a plate illustrating the little sedge *Carex microglochin* Wahl, the discovery of which at Glen Lyon, Perthshire, by Lady Davy and Miss Gertrude Bacon, is described by Dr. G. Claridge Druce, the secretary of the Club, as the great botanical event of the year In addition to the usual notes upon rare finds during the year, or references to interesting work upon British species and new county records, the report contains several papers of distinct interest to systematists, such as the paper upon British forms of Thymus by K Ronniger, Vienna, notes on British mints by J Fraser, on violets by E S Gregory, upon *Orchis maculata* L and *O Fuchsii* Druce, by G Claridge Druce Descriptive accounts of special areas of vegetation include that upon the vegetation of Beinn Laoigh (Perthshire) by Donald Patton, and of the Culbin Sands by E J A Stewart and Donald Patton The report closes with a very interesting illustrated account of the foundation of the Oxford Botanic Garden and its tercentenary by Dr. Druce No one is better qualified than this writer to evoke in a few brief pages memories of the many botanists officially connected with this historic botanic garden

IN his article on "Early Activities of the Royal Society," in NATURE of January 31, Mr. T E James referred to the election of Pepys and his undertaking in 1674/5 to provide a lecture for the Society. Mr. James was unable to find any record of Pepys having kept the promise or paid the fine in default, and he remarked that there was "no reference to this lapse in the well-known Diary." Mr C. Macnamara writes from Arnprior, Ontario, to point out that the last date in the Diary is May 31, 1669, that is, several years before Pepys made the promise mentioned in the article.

THE efficient equipment of observatories calls for the services of the engineer as well as the scientific-instrument maker and the optician. The firm of Messrs Cooke, Troughton and Simms, Ltd., Buckingham Works, York, are fortunate in having at their command facilities for the production of all the apparatus and equipment required for astronomical observation. Several well-known observatories have been built and equipped by the firm, and this branch of their production is now being further developed. A recently issued catalogue, No 570, contains a full list of astronomical instruments and apparatus manufactured by them, including domes from 10 to 40 feet in diameter, telescopes with objectives up to 20 inches in aperature, a full range of eyepieces, photographic and spectroscopic accessories and position micrometers. Portable equatorial and alt-azimuth stands, semi-portable and fixed equatorial telescope mountings and transit instruments, of various types, are described and illustrated, as well as mechanical and electrical accessories The articles included in the catalogue are all standard apparatus and instruments, for which prices are quoted; but the firm undertakes also the design and construction of instruments for special purposes.

Two important catalogues of second-hand books of science have just been issued by Messrs Wheldon and Wesley, Ltd, 2 Arthur Street, W C.2, viz. No. 15, Zoology, Part 2—Vertebrate Faunas, containing nearly 1500 titles, and No 16, Lepidoptera, with some 262 titles A number of scarce works are offered for sale, and the catalogues should appeal to many readers of NATURE

Our Astronomical Column.

MIRA CETI —There have been three interesting discoveries made concerning this famous variable in recent months The finding of the faint companion, that is responsible for the bright lines seen in the spectrum at *minimum*, has already been reported in this column The next step was the investigation of its heat radiation by the thermocouple by Messrs Nicholson and Pettit at Mt Wilson, this was described by Prof Eddington at the February meeting of the Royal Astronomical Society (see *Observatory* for March, p 58) While the visual magnitude varies from the third to the ninth, a 200-fold range, the "heat magnitude" varies only from 1·5 mag to 3 mag, a 4-fold range This shows that the loss of light is almost wholly in the short wave-lengths

The third discovery, reported in the *Times* of March 12, is that Dr F Pease has successfully applied the 20-ft interferometer on the 100-inch reflector at Mt Wilson to the measurement of the angular diameter of Mira, obtaining the value of 0·06″, which is the largest yet found for any star, though its linear diameter would be about equal to that of Betelgeuse, each being about 250 million miles, assuming that their adopted parallaxes are correct

It is evident that the surface brightness of Mira must be very low, since in spite of its greater angular diameter it is some two magnitudes fainter than Betelgeuse even when at its maximum light It will probably be followed for as long a portion of the light curve as the interferometer method permits, in order to see whether the diameter varies periodically. Such a variation was strongly suspected in the case of Betelgeuse, itself a variable but with a much smaller range

Mira is probably the nearest to us of the long-period variables, and anything found about it may be applicable to the whole class They were formerly thought to be expiring suns, but are now considered to be at an early stage of star-life

A NEW APPLICATION OF THE SPECTROHELIOGRAPH. —Mr Royds, Director of the Kodaikanal Observatory, described at the meeting on March 13 of the Royal Astronomical Society, a new method of using this instrument Instead of placing the second slit wholly on the H_α line of hydrogen, it was made to project on to the light spectrum, the character of the image was then found to be entirely different Instead of measuring the amount of light from glowing hydrogen in different regions, it now measures the varying pressure of the gas by the varying width of the line, and consequent reduction of light where it is broadest and the pressure greatest

Each sunspot is found to be surrounded by a narrow bright ring, outside this there is a large dusky region, showing a good deal of structure. The general mottling of the whole disc is very clearly brought out, and seems to have more regularity than in ordinary pictures The method is quite a hopeful one for bringing out some new points concerning the distribution of gases over the sun's surface

THE SYSTEM OF β-LYRÆ —Prof H. H Turner, at the meeting on March 13 of the Royal Astronomical Society, announced an interesting result which Miss Blagg has obtained She finds that there is a small subsidiary variation of light, the amplitude of which is about 0·1 magnitude, and period 6·595 days, very little in excess of the 6·454 days which is the half period of the main variation It is this approach to synchronism that has prevented the new term from being detected earlier It shows itself not as a separate curve, but as a slow alteration in the amplitude of the principal curve No suggestion was made of the explanation of this new term. As the two stars are supposed to be almost in contact, there would not seem to be room for a third orb in their immediate vicinity.

THE DISTANCE OF THE ANDROMEDA NEBULA —Prof. H N. Russell gives some further details in *Scientific American* for March of Prof. Hubble's investigation of the distance of this nebula by photographing the Cepheid variables in it He mentions the possibility that was alluded to in NATURE of March 7, p 349, that absorption by the nebula might diminish the stars' light and so give too large an apparent distance. But he says that several stars in different parts of the nebula agreed in giving the same distance, thus showing that the absorption effect must be very small, since otherwise it could scarcely be the same for all the stars Prof Russell also notes that stars that are individually visible in the nebula must be a thousand times as luminous as the sun; hence only the extreme giants are separately visible, and the great mass of the stars in it are only seen as a general glow. There is still something of a puzzle about the very rapid diminution of light as we pass away from the centre that was found by Mr. Reynolds's photometric measurements. This seems to indicate a different structure from that in our sidereal system.

Research Items.

PALÆOLITHIC MAN IN CENTRAL EUROPE.—L'Abbé Breuil continues his account of his "voyage paléolithique" in Central Europe in *L'Anthropologie*, t. 34, No. 6. He now deals with finds in the loess of Moravia and Bohemia, which are to be described in two sections, the first, which is the present instalment, covering open-air shelters, and the second the caves Three stations in Moravia are described: Premost, Ondraditz, and Brno (Brünn). As regards the human remains found at Premost, L'Abbé Breuil is of the opinion that the view of Dr. Hrdlička and Dr Matiegka, that Premost man represents a cross between Neanderthal man and the Aurignacian races, cannot be maintained. The prominent supraorbital ridges cannot be regarded as a decisive criterion against the absence of characters such as the remarkable platycephaly, the development and specialised character of the face, of the nose and orbits, and the receding chin of Neanderthal man—characters which are far more significant than the prominence of the supraorbital ridges The same applies to the Brno man. Both must be regarded as Aurignacian, differing from Aurignacian man in Western Europe, it is true, but also exemplifying the highly diversified character of the Cro-Magnon race, which was probably already a mixed race when it penetrated Europe.

ANTHROPOLOGY OF THE CHINESE.—Mr W W. Cadbury, of the Canton Christian College, contributes to the *Philippine Journal of Science* for December a study of the height, weight, and chest measurements of Mongolian peoples, with special reference to the Southern Chinese He has made a valuable digest of the literature dealing with these points and has added to it the results of his own observations on the students of the Canton Christian College The general conclusions at which he arrives are that the Chinese people average 165 cm. in height, the people south of the Yangtze being generally taller than those to the north of the river Cantonese students of 20 years or more average 163·6 cm The average weight for the Chinese is 56·9 kgm. in the north, 52·6 kgm in the south, Cantonese students 51·9 kgm. The weight-for-height index varies from 313 in the south to 384 in soldiers of the north. Cantonese students average 317. Chest circumference is relatively small, varying from 77 4 to 86·9 cm Cantonese students have an average circumference during rest of 78·9 cm. with a play of about 6 cm

CANCER AND GOITRE.—In a recent number of *Biometrika* (vol. 16, 1924, p. 364), Dr. Percy Stocks concludes, from a statistical examination of the data of several countries, that there is a distinct positive correlation between the rate of mortality from cancer of the stomach and œsophagus and indices of the prevalence of goitre. An analysis of post-mortem records also leads to the conclusion that enlargements and other anomalies of the thyroid, the anomalies being usually of the type associated with depressed functioning, are more frequent in cases of cancer than in other cases. On the other hand, there is some evidence of a negative correlation between the incidence of cancer and of Graves' disease Dr. Stocks thinks that these findings "seem to indicate that defective functioning of the thyroid gland is favourable to the incidence of cancer of the stomach, and possibly of other organs also."

SOUND PRODUCTION BY INSECTS.—An interesting critical paper on this subject by Mr. Frank E. Lutz is to be found in the Bulletin of the American Museum of Natural History, vol. 50, 1924, pp 333-372, and the conclusions arrived at by this observer may be briefly mentioned He remarks that, leaving out of account the Orthoptera and the cicadas, there are few or none of the sound-making insects that have well-authenticated organs of hearing, or the sound-producing organs of which may not quite conceivably produce the sounds by pure accident and without any purpose or profit. Until we have proof that insects in general purposely make sounds, or that they profit by sounds which they make without intention, there is nothing in our present knowledge of the biology of insects that furnishes good ground for believing that the few cases in which we hear insect-sounds are really exceptions to a rule that insects do not communicate by that means. In the cases of Orthoptera and cicadas, the presence of extreme specialisations, wonderfully efficient in producing sound and apparently not used for any other purpose, gives us a reason for thinking that there is a purpose The presence of what seems to be a definite ear in the stridulating Orthoptera is an additional reason However, when we see that the termites, which are not known to stridulate, have the same sort of an ear as crickets and long-horned grasshoppers, and that the cicadas, which produce a loud (to us) sound, probably have no ear (unless it be connected in a deafening way with the sound-producing structure), this latter reason loses some of its force If these structures have not arisen for the purpose of making sounds, why have they arisen, and how? There is at present no certain answer to this question. In a former paper (Lutz, Annals N.Y. Academy of Sciences, 39, pp 181-282) an attempt was made to show that complicated and definite structures, including details of wing-venation, had arisen by mutation or through the action of developmental factors without any "purpose" or favouring action of natural selection The author does not say that this is true of the cricket's wing and the cicada's drum, but he does not deny the possibility.

CHROMOSOMES OF *PARIS QUADRIFOLIA*.—Mr Bolles Lee contributes another paper (*Quart Journ Micro Sci*, vol. 69, part 1) on the structure and division of chromosomes In a study of *Paris quadrifolia*, he finds that the chromosomes contain a spiral perlaxial filament and are surrounded by a sheath Various observers have described such a spiral, others have interpreted it as a row of alveoli The small sizes of these structures renders their interpretation one of great difficulty The most surprising conclusion drawn is that the chromosomes always divide transversely in the telophase of mitosis, and never longitudinally at all We can only say that much more convincing evidence would be required before such a view could be regarded as at all probable Practically all of these results have been controverted by Martens (*C.R Paris Acad. Sci.* t 179, p 1280) in a preliminary paper in which it is also claimed that a reticulum of delicate threads can be demonstrated in the living "resting" nucleus and is therefore not created by fixation methods

SOME NEW GREGARINES.—B L. Bhatia and S Setna (*Parasitology*, vol 16, p. 279, 1924) record the occurrence of a cephaline gregarine, probably a species of Leidyana, in the alimentary canal of a carpenter bee, *Xylocopa æstuans*—the first gregarine to be described from a hymenopteran host The parasite occurs in large numbers throughout the length of the alimentary canal in every carpenter bee examined, but although the investigation extended

over several months, neither cysts nor spores were met with. The authors suggest that these stages probably occur within the larvæ of Xylocopa. They also record the occurrence of a species of Leidyana in the parenchyma of the polyclad Leptoplana.

COPEPODA OF THE CHILKA LAKE.—Major R. B. Seymour Sewell records (Mem. Ind Mus., vol. 5, pp. 771-851, 16 plates, 1924) the results of his examination of the copepod Crustacea of the Chilka Lake. Of the fifty-seven species present in the collection twelve are regarded as new, and five new varieties are also described. The author gives an account of the changes in the copepod fauna correlated with the varying conditions of the water, *e.g.* the influx of sea-water during the winter months causes a disappearance of the purely fresh-water species which had been carried into the lake during the monsoon. He remarks upon the number of species, hitherto regarded as being typical inhabitants of north temperate or even arctic seas, present in tropical waters. The breeding seasons of many of the species are noted.

HYDRA CHIMÆRAS.—Mr. V. Issayer describes an extended series of experiments (*Journ. Genetics*, vol. 14, No. 3) in producing animal chimæras by grafting together in various ways two species of Hydra, a stalked form of brown colour (*Pelmatohydra oligactis*) and a red variety of *Hydra vulgaris* found near Leningrad the cells of which contain carotinoid and lycopinoid pigments. The former species also has longer tentacles. By pinning together two specimens which had been opened out flat, by inserting an individual of one species into the cavity of another, and by other methods, chimæras were obtained the components of which could be followed by their colour. Mosaics were also obtained by cutting up Hydras into fine pieces and moulding the fragments together. Parts of some chimæras were intermediate in character and were called cytomictical. (It may be pointed out that the term cytomyxis is already in use in cytology in another sense.) Such individuals frequently reverted in buds to *oligactis* but never to *vulgaris*. The bearing of these results on problems of individuality, divisibility, regulation, somatic mutation, and other topics is discussed. A cytological study of these forms is being made which will throw more light on their nature.

SOUTH AMERICAN FUNGI.—Under the title "Fungi Paraguayenses," Carlos Spegazzini describes in the Anales del Museo Nacional de Historia Natural de Buenos Aires, vol. 31, some 267 species and forms of fungi collected by him during a visit to Asuncion in 1920. Many new species are described and figured, spore sizes and figure as well as other microscopic data being supplied.

POISONOUS PLANTS AND LIVE-STOCK.—In the *Kew Bulletin* (No. 1, 1925), J. Burtt Davy has an interesting note underlining the value of scientific investigation of the causes of losses to live-stock as the result of local peculiarities in the quality of the grazing grounds. He uses as a text the important reports upon "Gauwziekte Veld," by Sir Arnold Theiler and Dr. Pole Evans, which have recently been published by the Department of Agriculture, South Africa. The nature of the injury to stock thus produced may be estimated by the fact that one farmer lost 1047 sheep (59 per cent. of his flock) after grazing them for less than twenty-four hours on gauwziekte veld. After prolonged inquiries lasting over ten years and feeding tests with 98 species of plants, these investigators definitely proved that the cause of the losses of stock was *Vangueria pygmæa* (Rubiaceæ). This plant appears to contain a toxic principle, acting directly on the heart, though the toxin has not yet been isolated. Other cases of toxic species in grazing grounds are referred to by the author, who is thus able to make out a strong case for the work of a Government Department of Agriculture by which alone long and extensive investigations, involving the co-ordination of the work of specialists in different fields, can be both promoted and maintained until success is reached.

SYMBIOSIS OF SEEDS AND BACTERIA.—Gilbert J. Fowler and Miss R. K. Christie raise this question on very general lines in their paper in the Journal of the Indian Institute of Science, vol. 7, part xiii. They say that every seed they have examined so far has proved to be associated with specific bacteria either within the seed (poppy), within the husk (rice) attached to the seed by the mucilage coat (*Cassia tora*), or on the testa (indigo-seed). These bacteria are not essential to the germination, but do appear to be helpful in the growth of the seedling. Little difficulty appears to be raised by the authors' conclusion that these bacteria can break down protein reserves, but it is not clear how this property could be utilised by the germinating seedling. An interesting point is raised by the suggestion that the growth of these bacteria is associated with the specific seed extractive, apparently of basic or glucosidic nature, and removable by water or other suitable solvent, which every seed examined appeared to contain. This extractive did not prove on examination to be invariably antiseptic, but it is suggested that, on dilution during germination, it may stimulate the growth of the bacteria associated with the seed whilst holding them in check so long as it is concentrated, as in the resting seed.

CLIMATIC CONDITIONS FOR COTTON GROWING.—Mr. E. E. Canney has carried out a useful piece of work in analysing the climatic conditions required for the growth of cotton without irrigation (Journal of the Textile Institute, vol. 15, p. 1533). He finds that three conditions are essential: freedom from frost during the growing season, adequate but not excessive rainfall, and abundant sunshine. The cloudy, humid climate of large areas of the tropics is fatal to the economic production of cotton of good quality. The mean annual temperature should be above 60° F., the rainfall between 20 and 60 inches per annum, and the mean cloudiness less than five-tenths. On this basis he has prepared maps showing the areas where climatic conditions are favourable for cotton growing, and he finds that there are large parts of the British Empire, awaiting development, with suitable climates for growing as much cotton as is likely to be required for a long time. In the text, and still more strongly in an accompanying letter, Mr. Canney points out the urgent need for trustworthy meteorological observations from many more stations than at present exist in tropical regions. The lack of information as to climate retards development, and may lead to expensive failures owing to attempts to grow crops in regions which are climatically unsuitable.

ATOMIC WEIGHT OF BROMINE.—The January number of the Journal of the Chemical Society contains a paper by H. V. A. Briscoe and P. L. Robinson on the atomic weight of bromine. Ammonium bromide was subjected to 2700 fractional crystallisations from water, the object being to test Richards and Hall's conclusion that isotopes are inseparable by fractional crystallisation. No evidence of separation

was obtained. From the ratio Ag/AgBr, the atomic weight of bromine was found to be 79·914 ± 0·01.

CHLOROPHYLL SPECTRA.—Jan Wlodek has an ingenious suggestion to account for the differences observed between the spectra of chlorophyll in the living leaf and in various solvents. By combining the absorption spectra given by Willstätter and Stoll for chlorophylls *a* and *b*, he obtains a spectrum with absorption bands very closely coinciding with those of the living leaf, far more so than does the absorption spectrum of the alcoholic solution of the mixed pigments. He suggests therefore that in the living leaf the two chlorophylls are present in separate solvents, and that the changes in the absorption spectrum of the leaf under insolation are due either to the proportion of the two pigments changing, a fact that Willstätter and Stoll failed to establish by their classical analyses of the pigments, or that new spectra are developed as the result of temporary combination with carbon dioxide The paper is published in English in the Bulletin de l'Académie Polonaise des Sciences et des Lettres, Séries B, Science Naturelles pp 407-423, 1924, as a contribution from the Jagellonian University of Cracow

ABSORPTION OF RADIATION BY THE EMITTING ATOM.—In the *C.R. Acad. Sci. Paris* of January 19 M. de Broglie and J Thibaut describe measurements of the intensities of the corpuscular lines, due to the conversion of the *K* radiation of tungsten (doublet α) in an element, and of the *K* fluorescence lines of the element itself. The relative intensity of the second, with respect to the first, increases regularly with the atomic number for copper, silver, iodine, and barium. Bragg's law, combined with that of Moseley, would indicate a variation in the opposite direction In the case of radioactive transformations giving β- and γ-rays simultaneously, the β-ray spectrum being due to a photoelectric action of the γ-rays on the electronic shells of the disintegrating atoms, it is found that when the γ-radiation is converted into secondary photoelectrons in an isotope of the disintegrating substance, producing an identical β-spectrum, the intensities of the lines are much less than in the original spectrum of the radioactive substance. Using mesothorium and lead, the ratio of the intensities was found to be very roughly 1 · 10, indicating a much more intense absorption of mesothorium γ-rays in mesothorium than in lead Ellis has come to a somewhat similar conclusion on this subject, though he considers that in a γ-radiator the γ-rays are absorbed most strongly in the actual atom from which they are emitted, a point to which the authors have not directly given attention in their paper.

THERMOPILES IN THE LARGE SCALE MANUFACTURE OF GASES.—In the manufacture of hydrogen by the electrolytic process, it is very important to know at every stage the percentage of oxygen in the gas, and highly desirable to have an arrangement for sounding an alarm signal when the proportion of this impurity becomes too large. Dr. P. Gmelin, in the F. Paschen *Festschrift* number (January) of the *Annalen der Physik*, describes apparatus in which a small quantity of the gas is passed constantly through pressure regulators, half of the stream being sent through a tube of hard glass containing eight alternate thermal junctions of copper and constantan, and half through a similar tube, parallel to the first, which contains the remaining junctions. The two tubes are surrounded by an electric furnace, and in one of them pure platinum is deposited in the neighbourhood of the thermal junctions, to act as a catalyser for the combustion $O_2 + 2H_2 = 2H_2O$, the heat of the reaction being given up to the junctions. When no oxygen is present the registering millivoltmeter, to which the thermopile is connected, is not affected, and when the amount of this gas reaches 2 per cent. the deflexion is sufficient to make an electric contact and ring an alarm bell. It is arranged that this bell shall also ring when the current through the electric furnace is too low and when the gas stream is interrupted. The apparatus can be adapted to show the presence of 0 1 to 2 per cent of oxygen in nitrogen manufactured by the Linde process. Enough hydrogen is added to the test stream to combine with the oxygen and leave a small excess. Instead of the single pair of tubes described, as many as twenty-four pairs have been employed, to register from 0 01 to 0 5 per cent. of oxygen in mixtures of nitrogen and hydrogen.

THE PHYSICS OF SPRAY FLUIDS.—Rowland Marcus Woodman has two further papers upon this subject in the *Journal of Pomology*, vol 4, No. 2, January 1925. In the first paper is studied the influence of various substances in maintaining a suspension of lead arsenate, that is, in preventing its sedimentation, and it is pointed out that this is by no means the same property as that of lowering the surface tension of the liquid air surface so that the spray fluid readily wets the surface of the plants upon which it is discharged As the results of experiment, gelatine and calcium caseinate were found the most effective substances in promoting both these desirable ends, by fine grinding lead arsenate could be got into permanent suspension in water alone, but calcium caseinate, gelatine, or some other substance would still be necessary, in this case, to promote spreading In the second paper the advantages of the method of intermittent shaking for the preparation of emulsions of oil in water are studied and elucidated Gelatine and potash soaps prove to be much better emulsifiers than sodium soaps.

A NOVEL T-SQUARE.—A new T-square and drawing-board made by Axene Ltd, Maxwell House, Arundel Street, W.C, has been brought to our notice. The object of the invention is to "free the hands of" the draughtsman by providing a T-square which will retain its position on the board without any complication of cords or pulleys This is accomplished by the use of a magnet as the stock of the square, running on a steel strip in the edge of the board. The principle is not new, and previous inventions on these lines have not come into general use. The distinction of this square lies in the utilisation of the new magnetic cobalt alloy said to retain its magnetism almost indefinitely, and the whole of the stock is composed of this alloy. An examination of one of these boards suggests that, provided the length of the stock be proportioned to the length of the T in a ratio not less than found in ordinary squares, the T-square retains its position unaided, and assuming the retention of its magnetic properties, should be of considerable value to draughtsmen. These T-squares can be made with movable heads, but the leverage on the fixing screw on a long square is so great that a fixed head is usually preferred, at least for work which is mostly rectangular, and we did not observe any notable improvement in this respect in the square under discussion. Another useful feature of "The Axene" is the bevelling of the under side of the back edge of the square, enabling it to slide over drawing-pins. The drawing-board can be made with a steel strip on the bottom as well as on the left-hand edge, enabling the T-square to be used vertically and set squares to be dispensed with for work in which this position of the T-square is more convenient.

Forthcoming Books of Science.

Agriculture, Forestry, and Horticulture.

Ernest Benn, Ltd—Practical Butter and Cheese Making, L. J Lord, Market Nursery Work, six books on the cultivation of crops for market, F J Fletcher, cheap edition, Sugar Beet from Field to Factory, R. N Dowling. *Constable and Co, Ltd*—The Science of Soils and Manures, J A Murray, new edition *H M S O*—Report of the Departmental Committee on the Outbreak of Foot-and-Mouth Disease, 1923–24 *J B Lippincott Company*.—Agricultural Mechanics, R H. Smith *University Tutorial Press, Ltd*—Farm Calculations and Accounts, Dr. A. G Ruston; Farm Measurements (Mensuration), Dr. A. G Ruston

Anthropology and Archæology.

George Allen and Unwin, Ltd—Australian Totemism, G Roheim *J B Lippincott Company*.—Races, Nations and Classes The Psychology of Dominion and Freedom, H A. Miller *Macmillan and Co, Ltd*—The Ao Naga Tribe of Assam a Study in Ethnology and Sociology, Dr W. C Smith, with an Introduction by Dr J H Hutton. *Methuen and Co, Ltd*—Roman Folkestone, S E. Winbolt, Child-lore a Study in Folklore and Psychology, Mrs S Herbert *Oxford University Press*—The Life after Death in Oceania and the Malay Archipelago, Rosalind Moss, Prehistoric and Roman Wales, R. E M Wheeler *Kegan Paul and Co, Ltd*—A Geographical Introduction to History, Prof L. Febvre, The Dawn of Western Civilization, V G Childe, Race and History an Ethnological Introduction to History, Prof E Pittard, Mesopotamia the Civilization of Babylonia and Assyria, Prof L Delaporte, The Aegean Civilization, Prof G Glotz, Life and Labour in Europe XVth to XVIIIth Century, Profs G Renard and G Wentersse *H F and G Witherby*—Ancient Warriors of the North Pacific The Haidas, their History and Customs, with some Description of the Queen Charlotte Islands, C. Harrison

Biology.

D. Appleton and Co—Fishes, Dr D Starr Jordan. *A and C. Black, Ltd*—Bees, Wasps and Ants, Rev C A Hall, The Open Book of Nature, Rev C A Hall, new edition, How to Use the Microscope a Guide for the Novice, Rev C A Hall, new edition *Cambridge University Press*—The Anthocyanin Pigments of Plants, Muriel Wheldale Onslow, new edition, Plant Life on East Anglian Heaths being Observational and Experimental Studies of the Vegetation of Breckland, E P. Farrow, The Classification of Flowering Plants, Dr. A B Rendle, vol 2, A Comparative Hand-list of the Birds of Japan and the British Isles, M. U Hachisuka *Chapman and Hall, Ltd*—The Romance of the Fungus World an Account of Fungus Life in its Numerous Guises, both Real and Legendary, R. T Rolfe and F W Rolfe *Christophers*.—Evolution, Heredity and Variation an Introduction to the Study of Biology, D. W Cutler, Sex at Chance, Cicely Monteith Erskine *J. M. Dent and Sons, Ltd*—British Flora, G Bonnier, translation and adaptation to British conditions by Dr E Mellor *W Heffer and Sons, Ltd*—Studies in Ampullaria, E G. Alderson *Longmans and Co*—British Birds, A Thorburn, four volumes, Photosynthesis the Assimilation of Carbon by Green Plants, Prof W Stiles *Longmans and Co*—The Genera and Species of British Aphides, including their Food Plants and Distribution in Britain, together with a Host-Plant Index and Bibliography, Dr J Davidson *Macmillan and Co, Ltd*—Plants and Man a Series of Essays relating to the Botany of Ordinary Life, Prof F O Bower; A Class-Book of Botany, E Stenhouse *Oliver and Boyd*—The Science and Practice of Cattle-breeding, The Scottish Cattle-breeding Conference, July 1924, Animal Genetics, Dr. F. A. E Crew *Oxford University Press*.—Notes of a Naturalist in the East African Campaign, Dr G. D. Hale Carpenter, Plant Biology, Sir F W Keeble, Palms of India, Rev E Blatter, Microbiology of Cellulose, Pectins, and Gums, A. Thaysen and H. J. Bunker. *Sheldon Press*.—More Chats on British Mammals, Dr. J. J. Simpson *F Warne and Co., Ltd*—The Fishes of the British Isles: a Complete Pocket Guide dealing with the characteristics and habits of British Fish, both Fresh Water and Salt, Dr J. T. Jenkins.

Chemistry and Chemical Industry.

Edward Arnold and Co—An Elementary School Chemistry, E J. Holmyard, Physical Chemistry its Bearing on Biology and Medicine, Prof J. C Philip, new edition *Ernest Benn, Ltd*—Distillation in Practice, C. Elliott, Autoclaves and High Pressure Work, H Goodwin, The Conversion of Coal into Oils, Prof. Fischer, translated, edited with notes by Dr R. Lessing; British Chemicals: their Manufacturers and Uses, prepared for the Association of British Chemical Manufacturers. *Chapman and Hall, Ltd*—Colloid Chemistry, J. Alexander, Principles and Practice of Industrial Distillation, being a Translation of Hausbrand's "Die Wirkungsweise der Rektifizier- und Destillier-Apparate," Dr. E H Tripp. *J and A Churchill*—The Atmospheric Nitrogen Industry, Dr. B Waeser, translated by Dr E Fyleman *Gurney and Jackson*.—Lunge's "Sulphuric Acid and Alkali," new and revised edition, Vol 4 The Manufacture of Sulphuric Acid by the Contact Process, F D Miles; Introduction to Qualitative Organic Analysis, Dr. H. Staudinger, translated by Dr T K Braunholtz. *W. Heffer and Sons, Ltd*—Practical, Physical and Colloid Chemistry for Students of Medicine and Biology, Prof. L Michaelis, translated by T R Parsons, Practical Physiological Chemistry, S W Cole, new edition *Longmans and Co*—The Nature of Enzyme Action, the late Sir W M. Bayliss, new edition, The Fats, Profs J B. Leathes and H S Raper, new edition, Hexosamines and Mucoproteins, Prof P A. Levine, A System of Physical Chemistry, Prof W C M'C Lewis, Vol 2 Thermodynamics, new edition *Methuen and Co, Ltd*—Physico-Chemical Methods, Prof J Reilly, Prof W. N. Rae, and Dr T S Wheeler; Colloid and Capillary Chemistry, Prof H. Freundlich, translated by Dr H. S Hatfield; A Summary of Physical Chemistry, K Arndt, translated by W H Patterson *Oxford University Press*—History of Chemistry from Medieval Times to Dalton, E. J. Holmyard, Text-Book of Pharmaceutical Chemistry, A O Bentley and J Driver *University Tutorial Press, Ltd*.—Chemistry for Agricultural Students, R. H Adie.

Engineering.

Ernest Benn, Ltd—Notes on the Theory and Design of Continuous Current Machines, Dr S Parker Smith, new edition *Blackie and Son, Ltd*.—Steam Condensing Plant in Theory and Practice, J Sem *Chapman and Hall, Ltd*—Ports, their Administration and Operation, Dr. B. World Wheat Production.

DURING the past ten years it has been realised that all the countries in the world have a common bond in the international trade in wheat. Various adjustments in relationships have perforce been necessary, but the six years which have elapsed since the War have given wheat-growing countries time to stabilise their positions and in some degree to accommodate themselves, on one hand, to the cessation of export from Russia, and, on the other hand, to the discontinuance of the artificially enhanced production prevalent during the War years. For this reason the agricultural statistics for 1923 [1] published by the International Institute of Agriculture at Rome, with their comparisons with pre-War years, are of special interest, since they do at this stage indicate the trend which agriculture in general and wheat production in particular is taking throughout the world.

The situation as revealed by the year-book is, on the whole, reassuring Except in Europe, both area and production in wheat show an increase over the corresponding figures for the period 1909–1913. In North America the increases in area and production are approximately 40 per cent. The year 1923 was admittedly a favourable one for wheat growing, but an examination of the annual returns shows that this increase is not an isolated instance. Europe is still 7·3 per cent below its pre-War average in production of wheat, and 9·5 per cent below its average area in that crop over the same period ; but the area has increased steadily since 1920, and the production, notwithstanding fluctuations, has never fallen lower than it was then.

Russia is omitted from these returns, but the decrease in wheat production in that country during 1922, when famine conditions were at their worst, is now authoritatively stated as fifty-five and a half million quarters, or 65 per cent. of the pre-War average. In 1923 Russia had a small export trade. It will be remembered that, before the War, Russia was one of the chief sources of the world's wheat supply.

A good deal of attention has recently been directed towards the wheat production and crop balance-sheets of Canada and the United States. No appreciable decrease in area under cultivation in either country is

[1] International Year-book of Agricultural Statistics for 1923. Rome : Imprimerie de l'Institut International d'Agriculture, pp. xxv + 472.

recorded in the data published, but wheat production in both is less in 1923 than in 1922. Almost the whole of this loss can be apportioned to the United States, where increases in the more important crops of cotton and maize more than counterbalance it. Four million acres went out of wheat in 1923 and 5·4 million were added to the maize and cotton crops Further, the excess of exports over imports of wheat has fallen from 32 million quarters in 1921 to 9·6 millions in 1923. Taken together, these figures would seem to afford a striking confirmation of the forecast made by the Bureau of Agricultural Economics in the U S Department of Agriculture Year-book for 1921. In a paper on "Wheat Production and Marketing," O. E. Baker says, "Wheat production, however, has been increasing less rapidly than population in this country, and it is very probable that this will continue to be true, at least until we reach the point where we consume practically all we produce." Such a state of affairs is obviously of very serious import.

The International Year-book has grown during its brief career, and this issue gives many more details than its predecessors. It is to be regretted that in so doing it has been thought necessary to discontinue some of the summary tables. That relating to the percentage of each crop, based on total area under cultivation in each country, is a noticeable omission. The book contains sections dealing with crops, live-stock, trade returns, prices, freight charges, fertiliser consumption, and rates of exchange, and will repay perusal not only by the agriculturist and economist but also by the interested layman

Critical Ionisation Potentials.

THE publications in the Bulletin of the National Research Council of the Washington Academy of Sciences have included many numbers which are excellent reports on the state of knowledge at the time of publication in special branches of modern science. The monograph under review [1] is stated to be the first of a series which, when complete, will form the report of the National Research Council Committee on Ionization Potentials and Related Subjects. The monograph is in two parts, the first of which, by Prof. K. T. Compton of Princeton University, deals with the methods by which critical potentials for the excitation and ionisation of atoms and molecules by electron impacts have been measured. The author gives a very clear account of the principles of the various experimental methods of determining the critical potentials of gases and metallic vapours, and of investigating their significance. There is also a brief section on the critical potentials for the production of soft X-rays from solids. The text is well illustrated by diagrams of apparatus and experimental curves, which will be particularly appreciated by the general reader.

The second part of the work deals with the interpretation to be placed on the critical potentials which have been measured, that is to say, it is a discussion of the nature of the particular disturbance produced within the atom or molecule at each critical stage. It is written in a clear and concise manner by Dr. F. L. Mohler, of the United States Bureau of Standards. The relation between lower critical potentials and arc spectra is first given. Multiple excitation phenomena and the higher critical potentials of gases are then dealt with, and the interpretation of the latter class of data is further considered in connexion with the results for soft X-rays from solids. A final section deals with the results which have been obtained from experiments on polyatomic gases, and their relation to thermochemical data. The whole is illustrated by clearly drawn energy diagrams and Moseley curves.

The bibliography which is appended to the monograph is a very comprehensive one and will be of value to research workers in this field. Altogether the book forms the most complete summarised account we have seen of the work which has been done in the important branch of modern physics with which it deals, and the authors are to be congratulated on their excellent production.

[1] "Critical Potentials," by K. T. Compton and F. L. Mohler, Bulletin of the National Research Council, Vol. 9, Part 1, No. 48. Pp. 135. (Washington, D.C.: National Academy of Sciences, 1924.) 1.60 dollars.

University and Educational Intelligence

BRISTOL.—A lecturer in physiology will shortly be appointed, with duties to begin on October 1. Particulars of the post may be obtained from the registrar. The latest date for the receipt of applications for the lectureship is April 20.

CAMBRIDGE.—The Adams Prize for an essay on "The Physical State of Matter at High Temperature" has been awarded to Mr R. H Fowler, Trinity College. A Smith's Prize has been awarded to T G Room, St. John's College, for an essay on "Varieties generated by Collinear Stars in Hyperspace" F. C Phillips, Corpus Christi College, has been elected to the Amy Mary Preston Read Scholarship.

The subject for the Adams Prize for 1925–6 is "The Constitution of the Interior of the Earth and the Propagation of Waves through the Interior and over the Surface of the Earth" The adjudicators say that "the facts as to the propagation of earthquake waves may now be considered fairly well established, and a discussion is asked as to the deductions which can properly be drawn as to the constitution of the interior of the earth. Such questions may suitably be treated as the reflection, refraction and dissipation of waves at surfaces of discontinuity, if any, inside the earth, also the interior arrangements which would best account for the ordinary P, S seismological tables. A discussion might also be given as to how far the various suspected periodicities of earthquake phenomena, if real, must be attributed to a periodicity of external agents, and how far, if at all, they represent periodicities of free vibrations of the earth itself." The Prize, which is of the value of 240*l*., is open to competition of all persons who have at any time been admitted to a degree in the University

Grants have been made from the Worts Fund to Mr. T R. Parsons, Sidney Sussex College, towards expenses incurred in studying with Prof Orbeli of Leningrad the operative procedure used in research by the physiologists of the Pavlov School, and to Mr. K. de B. Codrington, Corpus Christi College, towards the expenses of a visit to India for the purpose of carrying out archæological research at Elura, Hyderabad State, and at Badami, Bombay Presidency, and of making moulds of the sculpture

It is proposed to erect the new Pathological Laboratory on the Downing site near the Biochemical Laboratory and the Molteno Institute of Parasitology.

Emmanuel College is offering to a research student commencing residence at the University in October 1925, a studentship of the annual value of 150*l*., which will be tenable for two years. Applications must reach the Master of Emmanuel (The Master's Lodge, Emmanuel College, Cambridge, England) not later than July 31. The award will be made on the evidence submitted by the candidates, which must include a brief statement of the proposed course of research and evidence of general ability and of special fitness for the proposed course of research.

GLASGOW.—The late Dr John Hall, a graduate of Glasgow, of St John's Wood, London, who died in 1909, left the reversion of one-half of his estate to the University, for the foundation of tutorial fellowships in medicine, surgery, and obstetrics, for the better equipment of the practical classes in these subjects, etc. Through the death of his sister, who has added half her own estate to that of her brother, the large endowment has now accrued, and may amount to some 50,000*l.* when the estates are realised. The benefaction will be of great use to the University's large school of medicine, which now exceeds in numbers and in clinical resources any other in the kingdom.

Dr J. S. Haldane, fellow of New College, Oxford, has been appointed Gifford Lecturer at Glasgow for the years 1926, 1927.

MELBOURNE.—Applications are invited for the professorship of agriculture and the post of research physicist. Conditions of the appointments may be obtained from the Agent-General for Victoria, Victoria House, Melbourne Place, Strand, W.C.2. The latest date for the receipt of applications is May 31.

APPLICATIONS are invited, until April 18, for the professorship of philosophy at the University College of Swansea. Particulars of the post may be obtained from the College Registrar, Singleton Park, Swansea.

AN election to Beit fellowships for scientific research at the Imperial College of Science and Technology, South Kensington, will take place in July next. Applications must be received on or before April 18. Forms of application and all information can be had by letter addressed to the Rector of the College.

VISCOUNT BURNHAM will deliver an address on "Technical Education as it affects Employers of Labour" on Friday, March 27, at 8 P.M., at the Battersea Polytechnic, London, S.W.11. The Governing Body of the Polytechnic has extended an invitation to the London County Council Joint Standing Conference of Evening Institutes in the district to hold at the Polytechnic an Exhibition of Work done by students on Friday evening and Saturday afternoon and evening, March 27 and 28, while the laboratories, workshops, kitchens and demonstration rooms of the Polytechnic will also be open for inspection.

SOME of the inner working of a preparatory school on modern lines is shown in a pamphlet entitled "St. Piran's Year Book for 1924," recently received. Few people realise how fundamentally wrong is the system of so-called education in a great many preparatory schools where the only object seems to be to cram in a knowledge of a few subjects—principally Latin and Greek—to meet the requirements of the Common Entrance Examination. How this can be expected to encourage latent ability, even for languages, much less to reveal a boy's true bent, passes comprehension. Every schoolmaster admits what Mr. Secretary Cecil said to Roger Ascham, very wisely and most truly, when the great plague was at London in 1563: "Many young wits be driven to hate learning before they know what learning is." The headmaster of St. Piran's, Maidenhead, has shown in a very practical way how scholarships can be won and examinations passed without serious detriment to education in the true sense of the word. Natural science, for example, is taught to the boys at St. Piran's although the Common Entrance Examination does not require it. An engineering shop, various societies—literary, natural history, wireless, photographic, gardening—and lectures on subjects of current interest provide stimuli calculated to reveal latent ability. This is, or should be, the true aim of all education. To the impartial mind it appears that this out-of-date Common Entrance Examination condemns the boys in most preparatory schools to do merely school work in school, while the education, if any, they may have the luck to acquire is most likely to be picked up in out-of-school hours.

THE Battersea Polytechnic's report for 1923–24 shows 2735 as the total number of students, 447 being full-time and 2288 evening and other part-time students. The full-time courses were chiefly in the Training College of Domestic Science, and in engineering. Of the entries for part-time work about a third were for mechanical engineering and building and electrical engineering, a third for physics, chemistry, and mathematics, and the rest for women's subjects, music, hygiene and physiology, matriculation classes, physical training, and art. The figures are large, but a comparison with the figures for previous years is disquieting. The Principal points out that there is a steady decrease in numbers, and says it is largely due to the increased fee for out-county students (to cover the difference between the ordinary fee and the cost to the L.C.C. of the student's education) and the cessation of work under the Government scheme for the higher education of ex-service students. The decrease in the number of full-time students is fully accounted for by these reasons, but there remains a large decrease, nearly 600, in the number of evening students (comparing 1919–20 with 1923–24), attributable in part it may be supposed to the slump in the engineering trades. An interesting development in the Department of Hygiene and Public Health is the institution of a course in practical home dietetics (gas-ring or oil-stove cooking) for bachelor men and women. The enrolments in this department show a substantial increase.

THE international interchange of university students and university teachers has attracted much notice since the War. Many post-War organisations—the League of Nations' Committee on Intellectual Co-operation, the International Confederation of Students and its affiliated national unions, and many others, as well as older associations, such as the League of the Empire and Victoria League, make the fostering of such interchange one of their chief objects. The Universities Bureau of the British Empire has an Interchange Committee, consisting mainly of the Interchange Correspondents of the Bureau in the home universities, and has for several years printed and circulated annually a list of students from other countries in the universities and university colleges of Great Britain and Ireland. To the list for the current academic year is appended a list of university professors and lecturers of these universities who in 1923–24 visited universities in other countries and vice versa. No official sources of information exist regarding the visits of university teachers, since many of them are arranged without the official cognisance of the registrars of the home universities: indeed, the list is so scanty as to suggest that the visits of these "merchants of light," as they have been called, resemble, in being few and far between, if in no other respect, the visits of angels. Nevertheless the list is interesting as a pioneer attempt which should be repeated with more success. When one considers the expenditure incurred in the world of finance and commerce in recording and publishing statistics of imports and exports of material commodities, one wonders that the learned world has not long ago insisted on receiving systematic intelligence of the interchange of savants.

Early Science at Oxford.

March 23, 1685–6. An abstract of Mr. Bent's travailes in France, was communicated by Mr. Welsteed, and read —Mr. Walker delivered in papers on an empiricall way of curing ye Cramp by a piece of ye root of fflag, and on Second-sighted men in Scotland, concerning whom Dr. Garden was desired to give his opinion.

March 24, 1684–5. Mr. Dalgarno advocated the bringing of a Philosophicall Language into practice He also presented a compendium of a book, not long since printed by him, entitled *Didascolcophus*, which among other things undertakes to prove, that the Eye & Hand are more useful organs of knowledge, than the Tongue and Ear. This gave occasion to some discourse concerning the Vigour and improvement of some one Sense, upon the Defect, or non-employment of one or more of the others, upon which subject Mr President was pleased to informe us, that Mr. Whaly (the deaf gentleman, whom he taught to speak) could, when within doors, distinguish a coach from a cart in ye street by the motion, it made, when those, who were in company with him, could not discern whether it were the one, or the other, by the noise, it made.

March 26, 1684–5. Ye Rt. Honorable the Lord Visct Weymouth, in answer to Dr. Plot's queries, concerning ye splitting of Trees by ye late Frost, wrote that great damages in this kind have befallen ye timber trees in most of ye northward midland counteys, but very little or none in ye western counteys of England

Ordered that ye thankes of this Society should be returned to Mr. Molineux of Dublin for his ingenious discourse concerning ye Petrifications of Loughneagh. in which it having been affirmed, that these petrifications are sometimes found in ye earth near ye Lough, it was queried, whether ye earth, in which these petrifications are sometimes found, may be supposed to have been thrown up from ye Lough? It was then proposed by Dr Beeston, that ye Petrifying Springs in, and near Oxon, should be strictly examin'd, particularly as to their chymicall principles, and that enquiry should be made into ye severall steps, and progress, of their respective petrifications —Mr. Packer, Physitian of Reading, gave an account of some observations he made lately in ye dissection of a Bear; particularly that there was no *Cæcum*, & that ye æsophagus consisted of so narrow a channell, and ye stomac, and entrails, are so well fixed in ye abdomen, that it was altogether impossible, they could at any time fall into ye mouth, as it was formerly supposed it might be in some postures of this animall It was ordered, that thankes should be returned to Mr. Packer, and that he be desired to continue a correspondence with us.

March 27, 1688. Dr. Plot gave the Society the sight of a Paper written for his Majesty's use, about felling Timber in Staffordshire, where they bark their trees in the spring and cutt them down in winter, which hardens the timber, soe that the outside is as hard as the heart of the tree. For felling wood in winter he brings the authority of the antients, Pliny, Theophrastus, Cato, &c. for the advantage of it. He shewed how the barking of it in the summer farthers the hardening by closing the pores in the evaporation of the juice by the heat of the sun. There is no objection against it but that t'will be more troublesome to fell the Timber so hardened, and to bark it standing, and so dearer, but the goodness will sufficiently answer the price.

Societies and Academies.

LONDON.

Royal Society, March 12 —Sir Charles **Sherrington**: Remarks on some aspects of reflex inhibition. Attempt is made to schematise in a diagram certain features of the interaction of central inhibition and excitation. Assumption is made of an inhibitory agent liberated centrally which neutralises chemically an excitatory agent when this latter is present, but the liberation of which is not dependent on pre-existence of the excitatory agent Tetanic inhibition is dealt with as due to iterate production of the inhibitory agent, with exhibition of temporal summation and "recruitment" Central after-action, both inhibitory and excitatory, is attributed to temporary persistence of a residuum of the liberated inhibitory or excitatory agent The schema is designed to meet in particular the experimental data furnished by the knee-extensor under crossed excitation and ipsilateral exhibition. It does not attempt to deal with late successive effects such as successive induction and rebound —E G T **Liddell** and Sir Charles **Sherrington**. Recruitment and some other features of reflex inhibition. Under mere prolongation of an otherwise unaltered stimulus of the inhibitory afferent nerve, the central inhibitory process recruits more motoneurones as it proceeds The "stimulation-plateau" of the reflex contraction is more easily inhibited than the "after-discharge plateau" Experiments suggest that a reflex maintains maximal response of the individual "motor-unit" by a degree of central excitation which is commonly "supramaximal," *i.e.* of intensity above the lower limit required for evoking the unit's maximal response In the excitatory reflex a mechanism proximal to the motoneurone axon seems to react in an "all-or-none" manner when exposed to inhibition —D. T **Harris** Studies on the biological action of light Ultra-violet radiations exert a stimulant action on the gaseous metabolism of small animals, and on the movements of the frog's isolated stomach This action is completely annulled by the presence of visible radiations, an action which seems to be physiological antagonism rather than physical interference Exposure of an animal to mixed radiations of a powerful source of light depresses its heat production to an extent greater in pigmented animals than in albinos for the same rise of temperature in the surrounding medium. Thermo-electric measurements indicate that pigment, nevertheless, possesses high absorptive properties Pigment appears to protect an animal against the lethal action of certain photo-dynamic substances —H. **Hartridge** and F J. W **Roughton** The kinetics of hæmoglobin III Velocity with which oxygen combines with reduced hæmoglobin The reaction between oxygen and reduced hæmoglobin is very rapid, the time required for half-completion being 0·01 to 0·001 sec The velocity-constants obtained at P_x 7 and P_x 10, with different concentrations of hæmoglobin and oxygen, agreed in showing that the reaction is bimolecular. The dissociation curve for dilute hæmoglobin solutions is approximately hyperbolic The quotient of the two velocity-constants, oxidation and reduction, is practically equal to the equilibrium constant The presence of hæmoglobin aggregates would not be expected to affect the velocity of oxidation, so long as the part of the molecule with which the oxygen combines is sharply localised and far removed from the aggregate-forming portion This affords an explanation of the low-temperature coefficient obtained.—S. B. **Schryver**, H. W. **Buston** and D. H. **Mukherjee**: The isolation of a product of hydrolysis of the proteins hitherto undescribed By

means of the "carbamate" method, a base $C_6H_{14}O_2N_2$ has been isolated from isinglass. It differs from the other basic products of hydrolysis of the proteins in that it yields a barium carbamate insoluble in water. It gives a tri-benzoyl derivative $C_6H_{11}O_2N_2(C_6H_5CO)_3$ m.p. 68-69°, and it is assigned the formula $CH_2 . (NH_2) . CH_2 \ CH_2 \ CH(OH)CH_2 \ (NH_2) . CO_2H$ It has been found after hydrolysis of fish gelatin, isinglass and three vegetable proteins of very diverse origin. It is absent from, or present only in very small traces in, the hydrolysis products of gelatin of mammalian origin, of casein, fibrin, and egg-white.—D. **Keilin**: On cytochrome: a respiratory pigment common to animals and yeast. Under names myohæmatin and cytohæmatin, McMunn described a respiratory pigment, here named cytochrome Cytochrome, in reduced form, shows a very characteristic spectrum, with four bands (*a*, *b*, *c*, *d*), with positions of maximum intensity *a*, 603, *b*, 565, *c*, 550, *d*, 523. In the oxidised form no absorption bands can be seen In different concentrations cytochrome exists in tissues of all animals, *e g*, worms, molluscs, arthropods and vertebrates It is also present in cells of ordinary baker's yeast, a thin layer of which shows well the above four bands The highest concentration of cytochrome is found in thoracic wing-muscles of insects, striated muscles of mammals, and yeast-cells It yields various derivatives similar to hæmochromogen and its oxy- and CO-compounds, and porphyrin Cytochrome may co-exist with other respiratory pigments, and may be considered an intracellular respiratory pigment, generally distributed, forming part of a complicated system of respiratory catalysts

Royal Microscopical Society (Industrial Applications Section), January 28.—R Stenhouse **Williams** The microscope of fundamental importance to the dairying industry.—Norman **Wright** The structure of the udder, normal and abnormal The solids-not-fat (lactose, protein, and ash of milk) are secreted in very constant concentration, owing probably to their osmotic properties, the fat bears no relation to the other constituents, since, owing to its insolubility, it has no osmotic pressure The control of rate of fat secretion is dependent upon the rate of formation in the gland (probably constant), and the fact that the cell membrane must be penetrated in order to liberate the fat globules The importance of correlation between the constituents of blood and of milk is emphasised.—A T R **Mattick** The enumeration and differentiation of the various cellular elements of milk, by means of the microscope On account of the enormous differences in numbers of cells found in the milk of different cows and even in different quarters of the same cow, no such standard can justly be adopted The method of differentiating between the various types of cells by the use of stains such as Jenners, and finding by means of the microscope the relative frequency of occurrence of the different types, is more promising Whilst the differential method of Varrier-Jones seems to offer considerable promise, more work on the varieties of cells found in different breeds and under different conditions must be done.—L J **Meanwell** The application of the microscope to the detection of tuberculous infection Great care must be exercised before assuming that acid-fast bacilli in market milk are of tubercular origin By the use of the usual routine method of microscopical examination, 20 per cent of infected milks are detected As this method is not satisfactory, animal inoculation must be performed before a report can be given. The disadvantages of the animal inoculation method of examination are said to be (1) Expense, (2) the lapse of time necessary before a report can be given, and (3) the difficulty in tracing the source of infection. 25 per cent. of milking cows are affected with tuberculosis, and in certain districts 4 per cent. of the milking cows show, on post-mortem examination, tuberculous lesions of the mammary gland.—J. **Golding**. Fat globules. "Adsorption films" of the nature of "gels" seem to explain the observations made on milk globules as well as on other emulsions. Observations on the differences in time of churning of the milk of individual cows support the conclusion of other workers that "individuality" may play at least as important a part as "breed" in this respect. The expense and difficulty of accurate estimations of size of fat globules do not encourage the use of the microscope in this direction. The microscopical examination of butter under polarised light yields more definite results in the comparison of butter and margarine.—Miss E R **Hiscox**. The separation and identification of the micro-organisms causing faults in milk products In the first method (moist chamber) a well-isolated cell is kept under observation under the microscope until the resultant colony is large enough to be transferred to a tube of culture medium In the second (Barber's method) small drops of an emulsion of the cells are blown on the lower surface of a coverslip by means of a micro-pipette Drops containing a single cell are transferred to tubes of the culture medium Although physiological reactions are of primary importance in the identification of micro-organisms, microscopical observation of the size and shape (bacteria), form of budding and spore formation (yeasts), form of branching and type of fructification (moulds), may also be of great value

Physical Society, February 13.—F E. **Smith** A system of electrical measurements. The study of the absolute measurement of electrical quantities, though usually regarded as difficult, is not beyond the comprehension of junior students if suitably presented The electrical units as theoretically defined and the practical standards by which they are represented differ, but an incorrect standard can be brought into more precise accordance with its theoretical unit without inconvenience to industry. The increased refinement of measurements calls for a redefinition of the practical standards, and this could be effected without inconvenience, since the most probable values of the standards lie within the limits prescribed by the errors permissible in industrial measurements

PARIS

Academy of Sciences, February 2.—Maurice **Hamy**: The determination of the radial velocities of stars. The application of the Doppler principle to the determination of the radial velocities of stars is now known to require certain corrections The alteration of the wave-length by pressure has been proved, and the Einstein gravitation effect must also be taken into account A. Michelson has also pointed out the necessity for another correction due to the fact that most radiations are not simple An international agreement relating to the comparison lines to be used in the determination of radial velocities is much to be desired.—G. **Bigourdan**: The perturbations of the Hertzian waves during transmission to great distances. A table is given showing monthly, quarterly and annual means; the general mean of the annual values is 0·013 sec.—André **Blondel**: A new method for the harmonic analysis of the curves of electromotive force of alternators. Two methods are described and discussed, one making use of a thermionic amplifier, the other working with a condenser.—Pierre **Weiss**:

The magnetic equation of state and variation of the atomic moment.—M. Eugène Fichot was elected a member of the section of geography and navigation in succession to the late E. Bertin.—A. Kolmogoroff: The possibility of the general definition of the differential, the integral, and the summation of divergent series.—J. Haag: Euclidian action at a distance.—P. Fatou: The movement of a material point submitted to the attraction of a flattened spheroid.—A. Barbaud and R. Le Petit: The measurement of the wind in an aeroplane and its effects on the route followed.—J. Cathala. A recording apparatus for the control of the insulation of enamelled wires. Enamel has been used in late years to an increasing extent as an insulating material for wires, but the wire thus covered always has a certain number of microscopic cracks, where the insulation is nil. In the apparatus described and figured the wire is rapidly drawn through a mercury bath and the weak spots detected.—Léon Guillet and Albert Portevin: The influence of tempering on the mechanical properties of steel after reheating. Whenever the nature of the metal permits the production of different constitutions by tempering, the results of mechanical tests obey the following rule: for equal final hardness after reheating, the resilience is better for the completely tempered states, that is to say, those formed of pure martensite. Inversely, for equality of resilience after reheating, the final hardness is always higher as the temper hardness is higher.—V. Auger and Mlles L. Lafontaine and Ch. Caspar: Some salts of cupferron. Details of the properties of 21 metallic compounds of cupferron.—O. Gaubert: The modification of the facies of crystals as the result of their syncrystallisation with a foreign material dissolved in the mother liquor.—Albert Michel Levy: The birth of biotite in the crushed granites and rhyolites of Morvan.—E. Tabesse. Magnetic measurements in Normandy and Brittany.—H. Hérissey and J. Cheymol. The extraction and properties of geine, a glucoside giving rise to eugenol, contained in *Geum urbanum*. This glucoside was extracted from the fresh underground parts of herb-bennet, in the proportion of about 0·1 per cent. On hydrolysis, it gives eugenol, *d*-glucose and *l*-arabinose in equimolecular proportions.—M. Bridel and C. Charaux: The process of blackening of Orobanche in the course of drying.—L. Blaringhem. New observations on Xenia in wheat.—Ad. Davy de Virville. The biological relations between a liver-wort (*Lophocolea bidentata*) and various Muscineæ.—N. Kleitmann and H. Piéron. The velocity of establishment of the light sensation and the magnitude of the undulation of pre-equilibrium for monochromatic stimulations of variable intensity.—E. Fauré-Fremiet: The quiescent state and active state in the amœbocytes of Arenicola.—C. Hosselet: The œnocytes of *Culex annulatus* and their chondriome in the course of secretion.—C. Levaditi and A. Girard: The mode of action of bismuth in syphilis. A quantitative method has been developed capable of detecting 0·001 milligram of bismuth, and this has been applied to the estimation of bismuth in various organs of the rabbit after treatment with trepol (alkaline tartro-bismuthate). Infinitesimal traces of bismuth (0·002 mgm.) are sufficient to destroy the parasite.

Effect of Phenols on the Sulphur Metabolism of the Dog.—Prof. J. S. Macdonald. Rectal Temperatures observed in Cycling Experiments.—W. Smith and L. B. Winter. Insulin and Micro-organisms.—L. N. Katz and C. N. H. Long: A Comparison of the Lactic Acid Content of Heart and Skeletal Muscle after Stimulation and in Rigor Mortis.—Prof. T. H. Milroy: Carbohydrate and Phosphate Metabolism in Muscles during Hyperglycæmia.—J. Hoet. The Action of Atropine on the Gut.—F. Avaling, R. J. S. McDowall, and H. Wells: The Physiology of the so-called "Psychogalvanic Reflex."—A. St. G. Huggett and Prof. J. Mellanby. The Action of Adrenalin, Ergotamine, and Curare on Muscle Tonus and Decerebrate Rigidity.—Dr. G. V. Anrep: Observations on Pulmonary Circulation.—H. N. Segall: The Isometric Contraction and Relaxation of the Frog's Heart.—Dr. G. V. Anrep and H. N. Segall: The Bainbridge Reflex.—H. E. Kinnersley, R. A. Peters, and J. T. Squires: Animal Quinoidine.—G. S. Adair: The Equilibrium of Oxygen and Hæmoglobin.

British Psychological Society (at Bedford College, Regent's Park), at 8.—R. H. Thouless: The Physics of the Psychogalvanic Reflex Phenomenon.—Rev. R. C. McCarthy: The "Determining Tendency" and Conation.

Royal Institution of Great Britain, at 3.—Sir Ernest Rutherford: The Counting of the Atoms (IV.).

Institute of British Foundrymen (Lancashire Branch: Junior Section) (at Manchester College of Technology), at 7.—H. Stead: Plate Moulding and the Patternmaker.

Hull Association of Engineers (at Hull Technical College), at 7.15.—Elce: Steam Turbines.

Ipswich and District Natural History Society (at Ipswich).—Dr. H. M. Cade. The Germ Theory of Disease (Pathogenic Bacteria).

MONDAY, March 23.

Royal Society of Edinburgh, at 4.30.—Dr. A. Balfour: *Reflections on Malaria*.

Victoria Institute (at Central Buildings, Westminster), at 4.30.—W. J. Bryan: Man and the Divine Image.

Royal Society of Medicine, at 5.30.—Dr. W. Hunter, Dr. R. Hutchinson, and others. Special Discussion (continued from February 16) on Non-specific Disturbances of Health due to Vitamin Deficiency.

Institute of Chemistry (Leeds Section) (at Leeds University), at 7.—R. B. Pilcher: Alchemists and Chemists in Art and Literature.

Institution of Electrical Engineers (*Informal Meeting*), at 7.—H. Grierson and others. Discussion on Panel Heating.

Institution of Electrical Engineers (North-Eastern Centre) (at Mining Institute, Newcastle-on-Tyne), at 7.15.—Col. T. F. Purves: The Post Office and Automatic Telephones.

Royal Scottish Society of Arts (at 117 George Street, Edinburgh), at 8.—Prof. W. Peddie: The Construction of Solid Materials.

Royal Society of Medicine (Odontology Section), at 8.—G. J. Harborow: A Dental Cyst in Connexion with a Deciduous Tooth.—A. Livingston: The Permeability of Enamel.

Royal Geographical Society (at Æolian Hall), at 8.30.—F. G. Binney: Across North-East Land.

Medical Society of London, at 8.30.—L. B. Rawling, Sir William Willcox, and others: Discussion on Oxaluria.

TUESDAY, March 24.

Royal College of Physicians of London, at 5.—Dr. J. A. Ryle: The Study of Gastric Function in Health and Disease (Goulstonian Lectures) (III.).

Royal Institution of Great Britain, at 5.15.—Prof. A. S. Eddington: The Internal Constitution of the Stars (I.).

Institution of Civil Engineers, at 6.—P. W. Robson: The Large Water-tube Boiler.

Institution of Electrical Engineers (East Midland Sub-Centre) (at University College, Nottingham), at 6.45.—Major E. I. David: Electricity in Mines.

Institution of Automobile Engineers (Informal Meeting) (at 83 Pall Mall), at 7.

Institution of Electrical Engineers (North Midland Centre) (at Hotel Metropole, Leeds), at 7.—H. W. Clothier: The Design of Electrical Plant, Control Gear, and Connexions for Protection against Shock, Fire, and Faults.

Royal Photographic Society of Great Britain, at 7.—J. F. Young: Perspective.

Institution of Automobile Engineers (Coventry Graduates' Meeting) (at Broadgate Café, Coventry), at 7.15.—C. Walker: Automobile Steels and Irons.

Institution of Engineers and Shipbuilders in Scotland (at 39 Elmbank Crescent, Glasgow), at 7.30.—Discussion on Internal Combustion Turbines, Prof. W. J. Goudie, and The Manufacture of Brass Condenser Tubes, with some Notes on an Alternative Alloy, G. H. Whiteman and A. Spittle.

Royal Society of Medicine (Surgery, Medicine, and Pathology Sections), at 8.—Sir Thomas Horder (Medicine), R. P. Rowlands (Surgery), and others. The Treatment of Septicæmia.

Royal Anthropological Institute (at 52 Upper Bedford Place, W.C.1), at 8.15.—Sir Aurel Stein: Innermost Asia. Its Geography as a Factor in History.

WEDNESDAY, March 25.

Geological Society of London, at 5.30.—C. Barrington Brown and R. A. Baldry: The Clay Pebble Bed of Ancon (Ecuador).—J. I. Platt. The Pre-Cambrian Volcanic Rocks of the Malvern Inlier.

Institution of Civil Engineers (*jointly with Institution of Mechanical Engineers, Institution of Electrical Engineers, Institution of Naval Architects, Institute of Marine Engineers, North-East Coast Institution of Engineers and Shipbuilders, Institution of Engineers and Shipbuilders in Scotland, Institute of Chemistry of Great Britain and Ireland, Institution of Gas Engineers, British Electrical and Allied Manufacturers' Association, British Engineers' Association*), at 6.—W. H. Patchell: A Standard Code for Tabulating the Results of a Steam-Generating Plant Trial.

Institution of Automobile Engineers (North of England Centre) (at 244 Deansgate, Manchester), at 6.30.—A. P. Burstall: Experiments on a High-speed Gas Engine.

North-East Coast Institution of Engineers and Shipbuilders (Newcastle and Middlesbrough Graduate Sections) (at Bolbec Hall, Newcastle-upon-Tyne), at 7.15.—Calderwood: The Possible Influence of Recent Research on Propeller Design.

Society of Chemical Industry (Newcastle Section) (at Armstrong College), at 7.30.—F. H. Walker: The Sampling of Coal.

Royal Microscopical Society (Industrial Applications Section), at 7.30.—Dr. J. A. Murray: The Making of Microscopical Preparations: (II.) Imbedding and Section-cutting.—Prof. P. Groom: The Microscopical Investigation of Fungal Attacks on Wood.—A. P. H. Trevelli and R. P. Loveland: The Application of Microscopy to the Photographic Industry.

Royal Society of Arts, at 8.—H. G. Dowling: Wall-papers.

British Psychological Society (Medical Section) (at Royal Society of Medicine), at 8.—Dr. J. A. Hadfield, Dr. J. Glover, and A. F. Shand: Discussion on The Conception of Sexuality.

THURSDAY, March 26.

Royal Society, at 4.30.—Prof. O. W. Richardson and T. Tanaka: *Regularities in the Secondary Spectrum of Hydrogen*.—Prof. S. Chapman. The Lunar Diurnal Magnetic Variation at Greenwich and other Observatories.—H. T. Flint: A General Vector Analysis with Applications to Electrodynamical Theory.—Miss M. O. Saltmarsh: The Spectra of Doubly- and Trebly-Ionised Phosphorus (P III and P IV).—*To be read in title only*: Dr. D. M. Wrinch and Dr. J. W. Nicholson: Laplace's Equation and the Inversion of Surfaces of Revolution.—Prof. T. R. Merton and J. G. Pilley: Experiments relating to the Spectrum of Nitrogen.—Prof. T. H. Havelock: Studies in Wave Resistance: the Effect of Parallel Middle Body.—T. Tanaka: Wave lengths of Additional Lines in the Many-lined Spectrum of Hydrogen.

Royal College of Physicians of London, at 5.—Dr. H. Cameron: Some Forms of Vomiting in Infancy (Lumleian Lectures) (I.).

Royal Institution of Great Britain, at 5.15.—T. Thorne Baker: Chemical and Physical Effects of Light (I.).

Royal Aeronautical Society (at Royal Society of Arts), at 5.30.—Dr. Eckener: Modern Zeppelin Airships.

Institute of Chemistry (Belfast Section) (at Queen's University, Belfast), at 7.30.—Dr. W. H. Gibson. The Union of Chemical Societies.

Institution of Automobile Engineers (Luton Graduates' Meeting) (at Luton), at 7.30.—Gibson: Maximum Performance and Balance of a Four-cylinder Engine.

FRIDAY, March 27.

Royal Sanitary Institute (at Town Hall, Leicester), at 3.30.—Dr. Helen Dent, Mrs. C. J. Bond, and others: Discussion on Maternity and Child Welfare Work.

Physical Society of London (at Imperial College of Science and Technology), at 5.

Royal College of Surgeons of England, at 5.—Sir Arthur Keith: Demonstration of Specimen illustrating the Commoner Congenital Malformations of the Lower Limb.

Royal Sanitary Institute (at Town Hall, Leicester), at 5.30.—Discussion on Smoke Abatement.

Institute of Marine Engineers, at 6.30.—Annual Meeting.

Manchester Literary and Philosophical Society (Chemical Section) (at 36 George Street, Manchester), at 7.

Institution of Mechanical Engineers (Informal Meeting), at 7.—Discussion on The Cutting of Heavy Steel Sections.

Royal Photographic Society of Great Britain, at 7.—H. Felton: *The Thames (Lecture)*.

Junior Institution of Engineers, at 7.30.—A. P. Morris: Irrigation Engineering in Burma.

North-East Coast Institution of Engineers and Shipbuilders (at Literary and Philosophical Society, Newcastle-upon-Tyne), at 7.30.—Eng. Lieut. Comdr. L. J. Le Mesurier. Conversion of the s.s. *Binsang*.

North East Coast Institution of Engineers and Shipbuilders (Middlesbrough Branch) (at Cleveland Scientific and Technical Institution, Middlesbrough), at 7.30.—S. Stanefield. Investigations of Stresses in the Rotating Parts of Steam and Internal Combustion Engines.

Royal Sanitary Institute (at Town Hall, Leicester), at 8.—Prof. H. R. Kenwood. Healthy Living—Facts and Fads (Lecture).

Royal Institution of Great Britain, at 9.—Sir Ernest Rutherford: Studies of Atomic Nuclei.

SATURDAY, March 28.

Royal Institution of Great Britain, at 3.—Prof. J. H. Ashworth: The Nervous System and Some Reactions (I.): Of Ciliate Protozoa and Sea Anemones.

PUBLIC LECTURES.

SATURDAY, March 21.

University College, at 3.—Dr. F. M. Feldman: Post-Natal Child Physiology and Hygiene (Chadwick Lecture).

Horniman Museum (Forest Hill), at 3.30.—S. Hazzledine Warren: Who were the First Men?

WEDNESDAY, March 25.

University College, at 5.30.—Prof. T. B. Wood: The Nutrition of the Young Animal (III.).

THURSDAY, March 26.

South Place Institute (South Place, Moorgate, E.C.), at 7.—Sir Arthur Keith: The Religion of a Darwinist (Moncure Conway Memorial Lecture).

SATURDAY, March 28.

Horniman Museum (Forest Hill), at 3.30.—H. N. Milligan: Living Animals of the Sea Shore.

SATURDAY, MARCH 28, 1925.

Scientific Officers in Tropical Agriculture.

MR ORMSBY-GORE, Parliamentary Under-Secretary of State for the Colonies, speaking at the annual dinner of the National Union of Scientific Workers on March 19, emphasised the need for many more highly trained scientific officers in British colonial possessions. His recent visit to East Africa with Major Church, secretary of the Union, as members of the East African Parliamentary Commission, revealed to him some of the problems which could be solved only by the use of scientific knowledge, and developments which can come from scientific guidance alone He regarded the present position as to officers and institutions concerned with tropical agriculture as "a disgrace to the Empire"

The earliest appointments of this class of scientific officers in tropical agriculture were the heads of the various tropical botanic gardens, usually systematic botanists, whose concern with agriculture was only a limited one, their principal duties being the introduction of possible useful plants, and the investigation of the local flora The first officer of a more specialist type to be appointed in the British tropical colonies was the late Prof Marshall Ward, who was sent to Ceylon in 1882 to investigate the coffee leaf disease (*Hemileia vastatrix*) and to endeavour to find some remedy for the already desperate position of affairs But his advent upon the scene was much too late for any remedy to be applicable that was within the means of the planters, and the visit was unsuccessful, so that public opinion was set against such appointments. A little later, however, the well-known Dr. Treub obtained quite a considerable staff of specialist scientific officers at the great Dutch colonial institute in Java, to which Mr. Ormsby-Gore paid high tribute

For a long time no further appointments were made in the British tropical colonies, and the next, so far as we are aware, was that of Mr E. E Green (now president of the Entomological Society), who in 1897 was made honorary government entomologist in Ceylon, with a small grant for expenses. In the following year, Mr. J. Parkin was appointed assistant in Ceylon to investigate the chemistry and physiology of the coagulation of rubber latex Mr. Green did such valuable work in his honorary capacity that in 1899 he was appointed full-time entomologist, while in the same year the newly formed Imperial Department of Agriculture in the West Indies appointed Mr. Maxwell Lefroy (now professor at the Imperial College of Science, South Kensington) as entomologist, and Messrs Harrison and d'Albuquerque as honorary chemists.

From that time onwards the number of scientific men employed in the tropical colonies has steadily increased,

though at first public opinion was opposed to such appointments, on the supposition that scientific work was unlikely to have much bearing upon practice in agricultural matters This expansion is to some slight extent due to an element of good fortune which attended these pioneers, who were markedly successful in their early work, of which that of the first two may be quoted as an example Mr. Green, with years of practical experience as a tea planter, made recommendations for the treatment of disease which were at once practical, economical, and successful, while Mr Parkin devised the method of coagulation of rubber latex which is still followed At first, the appointments were chiefly of officers to deal with diseases, or of chemists to deal with soil questions, and in this and other ways the old botanic gardens in some of the most important tropical colonies developed into Departments of Agriculture.

There are several essentials in the equipment of a scientific officer for the tropics, though naturally the training of each must vary with the duties which he is to undertake These essentials are well set forth by Prof Farmer in a pamphlet recently issued [1] In the first place, the officer must, of course, have a thorough knowledge of the science with which he is to be concerned, a knowledge best obtained at one of the universities, where he should have taken a good degree in honours. Next in importance is a good general knowledge of tropical agriculture, and (especially in the case of officers like entomologists, who have to make recommendations which involve the outlay of money) of the economics of the various cultivations. Such knowledge is best obtained in a tropical country, and if the individual cannot afford to spend some time at such a place as the Imperial College of Tropical Agriculture in Trinidad, he should learn his work by being attached as assistant to some officer with long experience of the tropics In the third place, the man should have a capacity for research, sufficient at any rate to enable him to find out the life-history of a disease, to test new plants or new conditions, to advise as to the best manures for unfamiliar soils, and such matters While this capacity is largely inborn, it may be much improved by work under a capable and experienced chief, under whom he may carry out definite pieces of research Finally, a most desirable part of the equipment is a capacity for giving—in speaking or in writing—clear and easily understood accounts of any work that has been carried out, whether his own or that of other workers It is through the work of men of this type, adequately trained and reasonably paid, that, as Mr Ormsby-Gore remarked, "we shall be justified in history as a great Imperial Power"

Philosophy and Science.

The Scientific Approach to Philosophy: Selected Essays and Reviews. By Prof. H. Wildon Carr. Pp viii+278. (London: Macmillan and Co., Ltd, 1924.) 12s. net.

FOR centuries past, science and philosophy, in spite of their common origin in the evolution of human thought, in spite, also, of the continuous (and inevitable) influence of each upon the other, have slowly but steadily drifted apart, both as regards their method and supposed subject-matter and as regards the avowed aims and general attitude of mind of their respective exponents During the past twenty years, however, there has been a marked reversal of this tendency; and it is fitting that Prof Wildon Carr should be one of the first to publish a systematic explanation of the causes and significance of the new movement, for he has done as much as any man to foster and encourage it.

Prof. Wildon Carr begins by pointing out that science and philosophy differ, not in their subject-matter, but in the mind's attitude towards it Philosophy seeks to see reality as a whole, but science is more concerned with particulars Philosophy proceeds from the whole to the parts, regarding the latter as significant only in their relation to the whole. Science, on the other hand, considers the parts as having reality in their own right, and proceeds, not to a systematic whole, but to invariable laws. It should perhaps be remarked that this view of the relation between science and philosophy is in fundamental contrast to that held, for example, by Mr. Bertrand Russell. For Mr. Russell, science and philosophy start from the same point and with the same material, namely, the particular facts of experience, and it is these particulars and the relations which subsist between them which are the essential concern of both. The difference between them lies in the fact that they proceed from their starting-point in opposite directions.

Prof Wildon Carr considers that science and philosophy have reapproached through biology and electromagnetism, or, more particularly, through evolution and relativity. The dichotomy of Nature as objective reality and mind as ideal representation, assumed by science, has turned out unworkable. Progress in science has raised, in connexion with science itself, metaphysical problems which are compelling us to reconstruct the whole basis of scientific thought The reproach, so often levelled at philosophy, that it is concerned with mere speculation regarding a transcendent reality, whereas science provides comparative certainty, is held by Prof. Wildon Carr to be due to the nature of the older idealisms. The "New Idealism," on the contrary, is the consciousness that the problems of science and philosophy arise from the

same subject-matter. It is in fundamental opposition to the "New Realism," for it regards activity and becoming as original, objects of ordinary experience as derived, and physical concepts as constructed; whereas the new realism assumes mind to be passive to the revelation of an external reality and active only in so far as it attends to what is thus presented.

Bergson and Croce are taken as the chief exponents of the new idealism The importance of Bergson lies in his substitution of the concept of pure duration for that of pure extension This implies that reality is fundamentally psychical, for only what is psychical "endures." Prof Wildon Carr goes on to a discussion of Bergson's theories of mind-energy and of memory, in the course of which he indicates what, in the present writer's view, is a complete refutation of the theory (still held by some men of science) that brain produces mind Briefly, his argument is that the theory in question leads to a contradiction and a vicious circle, for it can only infer the existence of the external world from the existence of brain process, while at the same time it is compelled to infer brain process from the existence of the external world of which the body is a part

There follows an interesting exposition of Croce's main theses, namely, that philosophy is not a science with a special (abstract) subject-matter, but a way of studying reality in its most comprehensive sense, while history is not the record of what was, but the interpretation of what is Hegel discovered the logic of philosophy—a special method of treating reality as a whole and not particular parts thereof; but he is criticised by Croce for failing to recognise that there are analogous logics of mathematics, science, history, etc., and for confusing the synthesis of contradictions with degrees of truth and reality

That portion of the book which deals with relativity will perhaps be of most interest to the scientific reader General relativity theory, if accepted, means the convergence of the two lines of intellectual development which we name science and philosophy. It reforms the notions of substance (ether) and cause (force), and implies that reality is "monadic" (*i.e.* constituted by "monads" or "minds" considered as metaphysical reals), the "universe" of physics and common-sense being dependent on subjects of experience in the sense that it is the co-ordination which they effect. In the result, materialism and natural realism cannot be indifferent to relativity, for their whole philosophy is at stake.

For philosophy in general, Einstein's scheme is superior because its constitution is inherent in experience and does not transcend the conditions thereof. It rejects an absolute *which is independent of experience*, and recognises as fundamental one of the chief tenets of monadism, namely, that there is no way of presenting the object of knowledge in complete detachment from the conditions of knowing

After an illuminating review of the work of Descartes and Pascal, Prof. Wildon Carr concludes with a discussion of intercourse by means of speech. The problem here considered arises from the fact that individual experience is private and yet there is intercourse The author argues, in this connexion, that language is not an invention due to our reasoning powers, but a product of evolution We speak because we are organised to produce and respond to articulated sounds Language is dependent on an internal psychical structure—we reason because we speak, and not vice versa

It is in respect of this problem of intercourse and interaction between minds that a weakness appears in Prof Wildon Carr's theories, and particularly with regard to the relation of body and mind, where it is argued that theory of intercourse is impossible if mind and body are distinct. But the difficulties of regarding mind and body together as one individual monad are very great For example, such a view cannot account satisfactorily for the fact that the mind's relation to the body has a twofold character. On one hand, a mind's relation to its own body is quite different in certain obvious respects from its relation to any other body, but, on the other hand, in no less obvious respects it is related to its own body (*e.g.* when it sees it) in the same way as it is related to all other material bodies. In fact, here and elsewhere, when dealing with this problem of intercourse and all that it implies, Prof Wildon Carr seems too prone to conceive interaction solely on the model of mechanical interaction. Indeed, on p 277 of his present work he says quite definitely that "intercourse between monads cannot be conceived as a form of *mechanical* interaction" But, quite apart from the fact that, if what he says about relativity is true, there is, strictly speaking, no such thing as *mechanical* interaction, he has not, in the writer's opinion, succeeded in proving that intercourse between monads may not be a type of relation which can fairly be termed "interaction," where action or activity is used in the sense in which he himself uses it, of monads or psychical reals, and not in the mechanical sense.

The book is written in Prof Wildon Carr's usual clear and eminently readable style. Though it consists of a number of papers given originally in comparative independence of one another, the thread of the author's thought is continuous throughout The theme of his study is of the greatest importance at the present time, and cannot fail to be of interest to all who wish to appreciate the real significance of the new convergence of those two streams of thought which have produced at intervals what are perhaps the noblest and mos profound creations of the human mind. C A R.

Chemistry and the Quantum Theory.

A System of Physical Chemistry. By Prof. William C. McC. Lewis. (Text-Books of Physical Chemistry.) Third edition. In 3 vols. Vol. 3: *Quantum Theory*. With certain Appendices by James Rice, A M'Keown, and R. O. Griffith Pp x+407. (London: Longmans, Green and Co., 1924.) 15s. net.

AN important test of the value of a scientific theory is its comprehensiveness. It is a curious and, in some ways, a significant fact that the most detailed account of the quantum theory published in Great Britain (apart from translations) is written by a professor of physical chemistry and appears in a series of text-books devoted to that subject There are signs that the boundary lines between "classical" physics and chemistry, almost unknown to Faraday, will again be obliterated and the two subjects become united in a theory of wider generalisation An Armstrong and an Arrhenius may worship together in a more magnificent temple dominated by the genius of Niels Bohr Chemists and physicists will no longer use different names for the same thing, but hark back to the point of view of Faraday, thus expressed by Poynting: "The hypothesis with which we start is that electrical and chemical forces are identical, that electrification is a manifestation of unsatisfied chemical affinities and that chemical union is a binding together of oppositely charged atoms or groups of atoms"

We are all agreed that matter may be described as composed of light negative electrons and more massive positive electrons or protons. We are all agreed that radiation may be regarded as an electromagnetic disturbance. To complete the picture we are forced by experimental facts to accept the two main postulates of Bohr: (1) Atomic systems can exist in certain "stationary states" which may be discussed by help of the ordinary electrodynamics in association with the appropriate quantum restrictions; (2) the passage of the systems between different stationary states cannot be treated by the classical theory, but involves, in some unexplained way, the emission or absorption of an amount of homogeneous radiation defined by the energy quantum $h\nu$, the product of Planck's constant h and the frequency ν. The foundations of the theory are discussed in an able manner in the appendices to the volume under review, and a special word of praise must be given to the lucid account of the "correspondence principle" by Prof James Rice Bohr's first postulate leads directly to the conception of energy levels, each such level being appropriate to a particular arrangement of the constituent charges of atom or molecule. It may be well to emphasise the importance of this conception in connexion with the problem of reaction velocity discussed by Marcelin and by Rice. The applications of the second postulate described in the volume are many, and it is possible to refer only to two which have recently attracted much attention.

The important photo-chemical law formulated by Einstein (1912) may be stated as follows: When light of frequency ν is incident on a system sensitive to such light, for each quantum of energy ($h\nu$) absorbed, one molecule of the absorbing substance is decomposed. It follows, according to this law, that the amount of substance acted upon by the light is proportional to the product of the absorbed radiant energy and its wave-length, and is independent of all other factors such as temperature. Most photo-chemical processes are complicated by secondary reactions which render it extremely difficult to test the direct applicability of the law It is, however, now generally admitted that *the absorbing molecule* absorbs energy in quanta. The experimental evidence is discussed in Appendix VII. by R. O. Griffith, who concludes that the ratio of the number of molecules decomposed to the number of quanta absorbed may vary over wide limits, though in a large number of cases its value is not far removed from unity. In a few reactions and within certain narrow spectral limits the ratio has been found to be unity. In the photo-chemical decomposition of hydrobromic and hydriodic acids, one quantum brings about the decomposition of two molecules, one molecule being decomposed directly, the other by a secondary process. But, in general, the ratio above mentioned is determined by processes which occur between the act of absorption and the production of the final products. Thus the final conclusion reached may be stated by saying that there is strong evidence in favour of the view that the ratio of the energy absorbed to $h\nu$ is equal to the number of absorbing molecules, but this number may differ considerably from the number of molecules decomposed. It is, accordingly, extremely probable that the primary process consists in the absorption of an energy quantum, but the subsequent changes are frequently so complicated that it is not at present possible to express them in terms of the quantum theory

The second question of great interest is the radiation hypothesis of chemical change first suggested by Trautz and discussed later by Perrin and the author of the present volume. Whilst the hypothesis accounts satisfactorily for the influence of temperature upon the velocity constant, it has not yet been shown that the hypothesis is capable of accounting for a velocity constant itself, the observed velocities being greatly in excess of those required by the hypothesis. Prof. Lewis sums up the position (in 1923) in a very fair way, without coming to any definite conclusion. He points out that the true analogue of thermal chemical change

on the radiation hypothesis is the thermionic effect, consisting in the emission of electrons due to the temperature of the material itself, and consequently due to the radiation density of all wave-lengths characteristic of the temperature of the material. The analogue of photo-chemical change is the photo-electric effect, in which electrons are emitted from a material owing to exposure of the surface to radiation from an external source at a relatively high temperature and usually of relatively short wave-length.

The reviewer has carefully compared the new edition with that of 1919 and finds that not only has the size of the volume been doubled but many desirable alterations and corrections have also been made. There are some points which require correction, but as the author remarks with truth, in such a rapidly changing subject it is exceedingly difficult to carry out the process of selection and condensation in a satisfactory way. Whilst the book cannot be described as a work of the very first rank, no serious student of advanced chemistry or physics can afford to overlook it. H. S. ALLEN.

Among the Natives of East Africa.

Beneath African Glaciers: the Humours, Tragedies, and Demands of an East African Government Station as experienced by an Official's Wife; with some Personal Views on Native Life and Customs By Anne Dundas. Pp. 238 + 28 plates. (London: H. F. and G Witherby, 1924.) 12*s.* 6*d.* net.

MRS. DUNDAS, as the wife of one of the Chief Commissioners (in the Kilimanjaro district), has had special opportunities for studying native problems on the spot, and these opportunities she has used to the utmost. It is admirable the ease with which she adapts herself to novel surroundings, making the best of everything, seeing something of interest in every place and object, whether at home or on the march. This is no small achievement when one considers the multitude of discomforts which have to be contended with in the climate of equatorial Africa; yet with a mind so active and so fully occupied with all that is going on around her, she is fortunate in having little time to dwell on these matters. Her sympathy with the inhabitants, and her power of expressing, in clear and pleasant language, the results of her observations and the conclusions she has come to, add a charm which is not often found in a book of this description. Existing and prospective officials, whose fate it may be to govern primitive races, could not do better than study closely what she has to say.

It is quite refreshing to read of the unsophisticated life the natives of this country lead—apparently happy—unspoilt, as yet, by the professional agitator, who earns his living by disturbing the "natural true contentment of spirit" in which man lives. The chapter on missionaries and their ways, and the conclusions the author comes to, are of much interest because of the important influence they are sometimes able to exert on the destinies of uncivilised people. One cannot help thinking that the author's views are sound common sense. What missionaries should do, when they begin to work among primitive races, is to devote all their energies to educating them, without trying to convert them, and without interfering with their native customs, for the latter often has the effect of undermining the authority of their chiefs through whom it is our policy to govern; any interference necessary in this direction should be left to government.

Mrs Dundas puts all this very well, and we must leave it to her readers to see how she does it. We may say, however, that her views appear to be those of a thoughtful inquirer, even on such a delicate subject as polygamy, deserving the closest attention of all who really have the welfare of native races at heart, and we hope her writings will bear some fruit. It is not the first time missionary methods have been criticised, but we are not sure criticism has produced much effect.

Mrs. Dundas has a good deal to say about Kilimanjaro, Africa's highest mountain, in sight of which she spent so much time. Two chapters are devoted to native manners and customs, and one to "big and little game" The book is well illustrated by scenes from life in Tanganyika, but a map is badly wanted, and if the volume is ever reprinted one should certainly be added. H. L. C.

Our Bookshelf.

L'Isotopie et les éléments isotopes. Par Mme. Pierre Curie. (Recueil des Conférences-Rapports de Documentation sur la Physique Vol. 9, 2e série, Conférences 1, 2, 3. Édité par la Société *Journal de Physique*) Pp. 210. (Paris. Les Presses universitaires de France, 1924.) 22·50 francs.

THE announcement that the first series of reports published under the auspices of the *Journal de Physique* was to be followed by a second series must have been welcomed by many physicists, to whom the task of keeping abreast of the manifold developments of the subject has become of daily increasing difficulty. The editors have been fortunate in their choice both of author and subject for this opening volume of the second series. There can be no doubt of the authority with which Mme. Curie speaks in all matters radioactive, or of her ability to marshal and expound her facts in a manner which makes them easy to grasp and assimilate. The fact that she has not been personally concerned in the more startling of the discoveries which she has to narrate is an additional advantage, as it has enabled her to exercise a critical discrimination not so

easily attained by one more intimately connected with the development of the subject.

The present volume is admirable, and covers a considerably wider field than might be expected from its title. It opens with an excellent synopsis of the chemistry, electrochemistry, and classification of the radio-elements leading up to a study of the radioactive isotopes. The following section deals with the isotopes of the non-radioactive elements, and the experiments of Aston, Dempster, and others. A third brief section is devoted to some interesting speculations on the structure of the atomic nucleus, and the volume concludes with a critical account of the methods adopted or proposed for separating the pure isotopes from the mixed element.

A full bibliography is appended Unfortunately, there is no index. The book is clearly printed and well illustrated with diagrams and plates, and its value is enhanced by numerous well-displayed tables. Mme Curie has collected in these 210 pages a mine of information, much of which can only be consulted elsewhere in original publications Both physicists and chemists should find this volume a valuable addition to their bookshelves. J. A. C.

Electrical Machinery and Control Diagrams. By T. Croft. Pp. xii+305. (London: McGraw-Hill Publishing Co., Ltd., 1924) 15s. net.

In practice, an electrician sometimes merely requires a circuit diagram of the apparatus or equipment with which he is working. He must therefore use symbols to denote electric bells, dynamos, etc., and show how they are connected with the accessory apparatus, such as switches, fuses, and regulating resistance coils. It is of importance that standard symbols should be internationally adopted. Considerable progress has been made in this direction by the International Electrotechnical Commission, and the leading countries of the world have sent in suggested symbols. Complete agreement, however, has not yet been obtained.

The symbols adopted by the author are those used by the Electric Power Club of America. They are very similar to those used in other countries. The 500 circuit diagrams given cover practically all of the apparatus used in a modern power or super-power electric station. The diagrams are of all degrees of complexity, beginning with the simple manually controlled starting rheostat and going on to the automatic substation. To the practical engineer they will be helpful. We hope that in the second edition of this book the author will be able to adopt international diagrams, and that he will also include diagrams for radio communication circuits.

Psychological Tests of Mental Abilities. By Prof. A. S. Woodburne. Pp. v+232. (Madras: Government Press, 1924) 2.8 rupees.

Although the method of mental testing is a comparative innovation in the field of education, its use is already almost ubiquitous. Most people know that it is widely employed in Europe and America, but perhaps fewer realise that its use has spread to Japan, China, Turkey, and, as the book under notice shows, to India.

Prof. Woodburne was invited last year to give a course of lectures on intelligence tests at the University of Madras, and he has extended his remarks to form a book. The larger part of it is a lucid description of the general principles of testing, and it shows evidence of wide reading and careful discrimination. Ample illustrations are given of the various types of linguistic, performance and vocational tests.

Some good work has already been done in India along these lines, and it is interesting to read of the necessary adaptations of standard tests in order to make them suitable for that country. Particularly illuminating also are the investigations of Prof. Haylands and of the author for the purpose of comparing the mental processes of the Indian and English adolescent. Indian educationists are keeping well to the fore in mental testing, for they have already planned a central clearing-house for results, and have suggested adequate instruction in testing methods for all their training college students.

In an Unknown Land. By Thomas Gann. Pp. 263+32 plates (London: Duckworth and Co., 1924) 21s. net.

The unknown land of which Mr Gann writes is Yucatan, which he visited with Dr S G. Morley for the purposes of archæological investigation. From Belize the party went northward and then westward on a two months' trip round the coast, making several inland expeditions to visit ruined Maya cities. Incidentally the book contains a great deal of information on a part of Central America that is little known and not easy of access, but its main value is the account the author gives of the Maya ruins and the Santa Cruz Indians. These form an independent tribe, since the Mexican government virtually evacuated their province, and represent the purest descendants of the Mayas. A great deal of work was accomplished, including visits to Chacmool, a previously unknown ruined city, Tuluum, which has always been difficult to reach owing to Indian hostility, and two minor new discoveries at Cancuen and Playa Carmen. All these are fully described. Of great interest are the accounts of the remarkable mural paintings of human figures and gods executed in bright colours on a hard stucco, found at Tuluum in a fresh condition despite their age of four centuries. The elucidation of the Maya method of dating in Yucatan was another striking discovery.

Graphic Statistics in Management. By W. H. Smith. Pp. vii+360. (London: McGraw-Hill Publishing Co., Ltd., 1924.) 20s. net.

The recording of business activity by graphical means is extending rapidly among the controllers of large businesses, and a book like the present volume, written primarily in the atmosphere of American big business, should be of especial interest in Great Britain. The whole subject is treated in picturesque graphical fashion; no mathematical symbol appears anywhere, and yet a considerable degree of analysis of financial and business activity, production, sales, markets, and costing is successfully effected. The chapter dealing with graphical statistics in advertising is capital, a large number of illustrations of varying character being shown, including one demonstrating the effect of advertisement on church attendance and Sunday morning offerings!

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Biographical Byways: Dr. S. P. Langley.

I REGRETTED to see Sir Arthur Schuster's article in NATURE of February 7 presented so unpleasing a picture of my old chief, Dr. S. P Langley. Like some other great men I have met, his character had blemishes, and, as one of Sir Arthur's anecdotes indicates, it was surprising to see in so great a man such care to preserve the appearance of dignity which he thought properly attached to his office and his attainments If he had been as careless of it as Lord Kelvin, dignity would have wrapped itself about him like a cloak, crowned with the mantle of lovableness, which, to his intimates, Langley surely possessed. One is reminded of the Scripture saying: "He that loveth his life shall lose it"

In regard to the eclipse of July 29, 1878, Sir Arthur Schuster's recollection is contradicted by Langley's own account Prof Cleveland Abbe, indeed, was carried down on account of sickness, but Langley, though at first ill, remained at the summit of Pike's Peak, observed the eclipse, sketched the corona to 12 diameters, and his report and sketch is to be found in the publications of the U S Naval Observatory (Washington Observations, 1876, Pt. 2, vol. 23, pp 203-10).

As a pioneer, Langley has to his credit the great forward step that he took in the spectral study of the energy of radiation of the sun, the moon, and terrestrially heated bodies. He was the founder of modern methods in this branch of science Also, he lent his prestige to rescue from the domain of ridicule the subject of mechanical flight, and investigated at great length, with novel devices, the reactions of moving surfaces in the air On the basis of these experiments he accomplished prolonged steady flight of quarter-sized engine-driven mechanical models, about eight years before the first human flying with power-driven aeroplanes took place. Except for bad judgment in shooting his larger machine from a house-boat, instead of allowing it to take off gradually as was proposed, engine-propelled human flight would have been made several years before it actually occurred. The blemishes of such a man ought not to blind us to his greatness.

I am happy, however, to be able to soften the implication of the final anecdote of Sir Arthur Schuster. He got the quotation, I suppose, through several mouths, and it is not accurate. When I was about to start on my first expedition to Mount Wilson, in the year 1905, Dr. Langley came to my office to talk over the plans. Months earlier we had discussed his value of 3 calories for the solar constant, and he was nearly convinced, I believe, that it had been based on an error of logic in the reduction of the Mount Whitney observations. Yet he did not desire to publish a retraction, for, as he said, "Mr. Abbot, I did that work when I was at the height of my powers. Now that I have been long out of the field, I am not more competent than I was then to reason upon it." He paused a moment, and added with a twinkle in his eye: "As the witty Frenchman has said, 'What has posterity done for us that we should care so much for the opinion of posterity?'"

So, when we finished our interview in April 1905, it was rather in the nature of good-natured chaffing than in the nature of an order when Langley said to me. "You will, of course, bear in mind that it is rather the *variation* of the sun that you are going to measure than the absolute value of the solar constant." The twinkle came again into his eye, as he continued: "In fact, Mr. Abbot, I might add that for me the best value of the solar constant is that which nearest approaches 3 calories!" and, as he always did when he had said a good thing, he turned quickly and almost ran away. It was the last time that I saw Dr. Langley alive.

Passivity of Iron and other Metals.

IT is well known that the principal metals which show the phenomena of passivity are chromium, manganese, iron, cobalt and nickel. These elements have this in common that they form divalent ions, and that while possessing electrons, *on* Bohr's theory, in the 4th-quantum orbit, their 3rd-quantum orbits are incomplete. My view is that these elements when in the active state have each two electrons in the 4th-quantum orbit, and that they become passive when one of these electrons is removed to a 3rd-quantum orbit. This implies that the usual chemical and physical agencies which make an active metal passive or a passive one active, merely, in some way, induce these electronic changes. It is for the physicists to say if this be possible. There is, however, no *a priori* objection to this view since transitions between 3rd- and 4th-quantum orbits of these elements are known to occur readily I do not suppose a suggestion of this kind will explain the whole of the phenomena of passivity, which is admittedly complex, but I offer it as a contribution towards the explanation of the more obvious phenomena.

Very few determinations of the electrode potentials of metals in the passive state have been published, and some workers have doubted if such determinations have any significance. I have found a simple way of preparing and keeping metals permanently in the passive state, and of comparing their electrode potentials with those of metals which do not show passivity. This consists in obtaining metals two at a time in mercury and comparing their powers of reducing solutions in sulphuric acid of uranyl sulphate, ferric sulphate, potassium permanganate and other oxidising agents. I find the order of the potentials of the metals in mercury is (proceeding from electro-positive to noble metals and including only those relevant to this discussion): zinc, cadmium, thallium, tin, lead, copper, manganese and iron, bismuth, cobalt, mercury, nickel and platinum. The order of these metals seems quite definite. It is the same whatever oxidising agent be reduced, whether the solutions be hot or cold, whether sulphuric or hydrochloric acid be employed, and whatever other metals are present in the amalgam. The order of potentials of metals in the free state is known to be: manganese, zinc, iron, cadmium, thallium, cobalt, nickel, tin, lead, copper, bismuth, mercury and platinum. A comparison of these two lists shows that only the metals known to show passivity fall out of order. The simplest inference is that the passive state is a quite definite condition, and that it is produced and maintained when the metal is amalgamated. This is consistent with Lambert's discovery that pure iron is a noble metal when its surface is electrically neutral.

The ions of these passive metals, however, do not behave as if they were the ions of noble metals. For example, ions of tin, lead and copper, but not of

cobalt, iron or nickel, are easily reduced to the metallic state by zinc amalgam in sulphuric acid solution. The order of the ions is probably similar to that of the metals when their electrode potentials are determined in the free state If this be so, it follows that elements which show passivity must have alternative configurations of planetary electrons, one of which corresponds to the configuration possessed by its ion. On present knowledge the number of electrons in the atom of iron is 2, 8, 14, 2 in the 1st-, 2nd-, 3rd-, and 4th-quantum orbits respectively, and in the ferrous ion 2, 8, 14, 0. If the latter configuration represents the ferrous ion, the former should represent the active iron because active iron passes readily into the ferrous condition Passive iron may therefore have one of the configurations 2, 8, 15, 1; 2, 8, 13, 3. Similar considerations apply to the metals chromium, manganese, cobalt and nickel When each of these elements has two electrons in the 4th-quantum orbit, it is likely to be in the active state and, when another number of electrons, it is likely to be passive

I think that this number is probably one because (*a*) it cannot be less, and (*b*) the agencies that are known to bring about passivity might possibly force one of the 4th-quantum electrons into a 3rd-quantum orbit This view receives some support from the following nickel is normally passive, that is, it differs from the other elements which show passivity in being rendered passive more easily than active. Now, according to Kramers and Holst, the configuration of the electrons in nickel is likely to be 2, 8, 17, 1. This on the views expressed here would represent the passive metal, and the alternative configuration 2, 8, 16, 2, from which the nickel ion is derived, would represent the active

I might add that metals when dissolved in mercury are far more efficient reducers in the presence of sulphuric acid than when in the free state. For example, tin, lead and iron are nearly one hundred per cent efficient when reducing ferric sulphate in sulphuric acid of different strengths, that is to say, these metals go into solution only in so far as it is necessary to bring about the quantitative reduction.

The Compton and Duane Effects.

THE experimental arrangement used by Compton has been such as to emphasise the fact that the change of wave-length represented by the most intense part of the modified line agrees with the formula

$$\lambda_\phi - \lambda_0 = h \text{ vers } \phi/mc, \quad . \quad . \quad . \quad (1)$$

where λ_ϕ is the wave-length of the X-rays scattered at an angle ϕ and λ_0 is the wave-length of the primary rays On the other hand, the experimental arrangement used by Duane has until recently been such as to emphasise the fact that very often the modified rays consist of a band of wave-lengths beginning at a wave-length change given by

$$\lambda_\phi - \lambda_0 = \lambda_0^2/(\lambda_s - \lambda_0), \quad . \quad . \quad . \quad (2)$$

where λ_s is a critical absorption wave-length of the scatterer More recently Allison and Duane (*Phys. Rev.*, 25, 235, 1925) by using smaller scattering blocks have found an agreement with (1), although they remark that there is a band of wave-lengths about this value This band nature of the wave-length change is also evident in Compton's curves (*Phys. Rev*, 22, 409, 1923). Some of the width of the band is due to the variation of ϕ in (1), but when the width due to this cause is subtracted from the width shown in Compton's curves, there is still some excess width. The writer has been able to explain this excess width by taking into account the momentum of the scattering electrons in their Bohr orbits (*Phil. Mag.*, in print) The electrons are moving in all sorts of directions, and hence we get a wave-length change varying from a minimum to a maximum, the width depending on the magnitude of the momentum of the electrons.

More recently, the writer (*Phys. Rev.*, in print) has been able to show that, if the binding energy is above a certain amount, and therefore the momentum of the scattering electrons above a certain other amount, the width given by taking into account the momentum of the scattering electrons alone is such that the minimum change of wave-length is less than that given by (2) However, the least possible change of wave-length is given by (2), because the recoil electron must be given sufficient energy to overcome its binding energy to the atom in order to be ejected. If the energy given to the electron by the scattering process is less than this, then the electron cannot be ejected from its Bohr orbit, and we may suppose that the mass of the rest of the atom is added to that of the electron. This causes m in (1) to be large, with the result that the change of wave-length is negligible.

Hence we have a quantum theory explanation of the existence of the unmodified line. Whenever there is an unmodified line produced by the scattering of X-rays by electrons of a certain type (*K*, *L*, etc.), then the wave-length change of the beginning of the modified band is given by (2) For example, when Mo$K\alpha$ X-rays are scattered at 90° by the *K* electrons of carbon, the modified band begins at a wave-length change of 0·012 Å U and extends to 0·057 Å.U The short wave-length limit of the modified band is in this case independent of the angle of scattering, which is in agreement with Duane's earlier experiments. The long wave-length limit, however, depends upon the angle of scattering Duane in these earlier experiments used a large scattering block, so that there was considerable variation of the scattering angle ϕ This variation of ϕ causes a variation in the long wave-length limit of the modified band, but not in the short wave-length limit. The theory indicates that with a given value of ϕ the intensity is approximately the same all over the modified band Hence with a large variation of ϕ the intensity would be greatest at the short wave-length limit of the band. This is the result observed by Duane.

The above is an explanation of Duane's results with a large scattering block. Compton, however, finds for $\phi = 90°$ that the wave-length change of the most intense part of the modified band is 0·0242 Å.U. Compton used a smaller scattering block and a spectrometer of less resolving power than Duane. With a small scatterer, the modified band would still extend from $\lambda_\phi - \lambda_0 = 0{\cdot}012$ to $\lambda_\phi - \lambda_0 = 0{\cdot}057$ Å.U. for the scattering of Mo$K\alpha$ X-rays by the *K* electrons of carbon. However, there are also *L* electrons in carbon. Of these the *L III* electrons move in circular orbits, and these *L III* electrons produce a modified band extending from $\lambda_\phi - \lambda_0 = 0{\cdot}0185$ Å.U. to $\lambda_\phi - \lambda_0 = 0{\cdot}030$ Å.U. The band does not in this case extend from the value of $\lambda_\phi - \lambda_0$ given by (2), and hence there are no unmodified rays scattered by the *L III* electrons at 90°. The centre of the modified band is seen to be at 0·0242 Å.U., the value given by (1) The *L III* band will be superposed on the *K* band; but the former will stand out more strongly since the theory indicates that the intensity (*i.e.* the energy per unit wave-length width) of the *L III* band is greater than that of the *K* band.

Hence, when a small scatterer is used the modified band shows great intensity at 0·0242 Å.U. The centre of this intense portion and its width depend, however, on ϕ. Hence for a large scatterer the intense portion becomes indistinct. Further, for a large variation of ϕ, the theory shows that the most intense part of the band due to the *L III* electrons is displaced to the short wave-length side of the value obtained by putting the average value of ϕ in (1). Large scatterers, therefore, tend to obscure the existence of the Compton wave-length change.

Still further, a spectrometer of low resolving power will show the Compton wave-length change better than one of high resolving power. With low resolving power the most intense part of the band comes at 0·0242 Å U. for $\phi = 90°$, whereas with high resolving power the band character of the modified rays is emphasised. For example, with high resolving power the $K\alpha_1$ and $K\alpha_2$ lines of molybdenum can be separated in the unmodified line, while the modified band will show no such separation, as each modified band overlaps the other due to its width. The absence of separation in the modified band might cause an experimenter using high resolving power to doubt the existence of the Compton effect

Transmission of Stimuli in Plants.

NATURE of January 17 has just reached me and I hasten to send a reply to Mr Snow's letter on this subject I repeat once more that in the numerous experiments which I carried out with the stem of *Mimosa pudica*, the stimulus was never transmitted across the water gap. Mr. Snow repudiates the idea that he has disagreed with my conclusions in regard to the conduction in the petiole of Mimosa. "Actually, however," he says in his letter, "in agreement with him [Sir J. C. Bose] I have produced evidence to show that in the leaf, excitation is conducted in the phloem and has nothing to do with the transpiration current. I agree also that this conduction in the leaf is, in all probability, a true physiological process, and consider that Sir J. C. Bose's experiments on the petiole, which so strongly support this view, are of very great value. In the stem, however, as I found, this conduction in the phloem either fails completely, or at least is regularly too weak to cause the leaves to fall."

Since it is admitted that conduction does not take place across a water gap in the petiole, Mr. Snow will note that there is a serious breach of continuity in the assumption that the mechanism of conduction in the stem is widely different from that in the petiole. We stimulate the leaf; excitation is transmitted along the phloem in the petiole and overflows into the stem, causing the successive fall of the leaves. Where does the hiatus in the conducting mechanism come in? The supposed conduction across a water gap in the stem has led to the theory that the transpiration current in the wood is the means of conduction of excitation. But the observation of Mr. Snow himself does not support this theory, for he finds, in opposition to Prof. Dixon, that Dr. Ricca's theory of the transpiration current is inadequate "to cover *all* the phenomena of conduction in Mimosa, including conduction in the leaf and the subordinate phenomenon of 'high-speed' conduction in the stem."

In my "Physiology of the Ascent of Sap" (1923), p. 269, I have clearly explained the modes of intercommunication and interaction between more or less distant organs of a plant. "This is accomplished in two different ways, by *transfer of matter* and by *transmission of motion*. The first is exemplified by hydraulic convection of liquids carrying chemical substances in solution, such as occurs in the circulation of sap; the second, in the conduction of excitatory change along nerves." These two can be easily distinguished from each other from the fact that the conduction of excitation is from a hundred to a thousand times quicker than the sap-movement of the transpiration current. A very simple experiment which requires no apparatus is to put a drop of hydrochloric acid on the tip of a leaf of *Mimosa pudica*: the acid remains practically localised, but the protoplasmic excitation induced by it is transmitted with considerable velocity, causing the fall of numerous leaves both above and below. This experiment, which can be repeated without any difficulty, completely demolishes the theory of the transpiration current.

I have, as stated in my previous letter, carried out numerous crucial experiments which fully establish the nervous character of the transmitted impulse in Mimosa. It has been a matter of surprise to me that reference to my work has been omitted in all letters and articles on transmission of stimulus in Mimosa that have appeared in NATURE during the last year This could not have been due to the obscurity of the journal in which my results appeared, for they were published in the Proceedings and Transactions of the Royal Society. The omission appears to me to be very curious; it cannot but obscure truth and thus divert the energy of workers in wrong directions which lead nowhere.

In this short communication I can make but bare mention of only a few of the results which I have recently obtained. The anatomical structure of the nervous tissue, made clear by selective staining of microscopic sections, has been found to be in every way the same in the petiole and in the stem. The distribution of the nervous tissue in the whole plant has been clearly traced, affording the fullest explanation of the transmission of excitatory impulse up and down and across the stem. The innervation of the contractile pulvinus, which functions as a muscle, has also been fully investigated, making possible a rational explanation of the purposeful movements by which the leaf places itself so as to absorb the largest amount of radiant energy. Still more striking is the success of my efforts to obtain, by means of selective staining, a definite outline of the rapidly contracting tissue in the pulvinus of *Mimosa pudica* No such staining occurs in the slowly reacting pulvini of other plants. This characteristic denotes the possession of a specific catabolic substance, and is highly significant These and other results prove that a very high and quite unexpected degree of differentiation has been reached in the nervous system of Mimosa I am in hopes of early publication of these results. In case of unforeseen delay, I shall take the opportunity of sending a short account of them for publication in NATURE.

The Behaviour of Crystals and Lenses of Fats on the Surface of Water.

DURING the last two years we have been interested in examining the behaviour of crystals and liquid lenses of fatty acids and esters when placed upon the surface of water.

Sir W. B. Hardy was the first to observe that the magnitudes of the surface tensions of the various

bounding interfaces for liquids, such as oleic acid, which spreads upon water, were in accordance with the theorem of Dupré,

$$\sigma_{H_2O} > \sigma_{Oil} + \sigma_{Oil\ water}$$

A lens of oleic acid, when placed upon a water surface of limited area, does not extend as a thin lamina of oil in bulk, but as a unimolecular film, by a process of two-dimensional solution or evaporation from the edges of the lens Equilibrium between lens and unimolecular oil film is finally attained when the rate of this process of surface solution or evaporation is balanced by the reverse process of condensation of oil molecules from the film The surface pressure of the film when equilibrium is established is defined by the equation—

$$\sigma_{\text{Contaminated surface}} = \sigma_{Oil} + \sigma_{Oil\ water}$$

We have noted that solid fatty acids and esters will spread on water surfaces until the surface tension of the water falls to a definite equilibrium value, but the rate of spread is much slower than for liquids

The beautiful experiments of Mr Adam have revealed the interesting fact that surface films may exist in two forms, the condensed and the expanded, the former being the two-dimensional prototype of solids and liquids, the latter of vapour Both crystals and liquid lenses can exist in equilibrium with both these condensed and expanded films, the equilibrium pressures being naturally different for each phase, and varying in a marked manner with the temperature, similar to the three-dimensional phase properties of solubility and vapour pressure

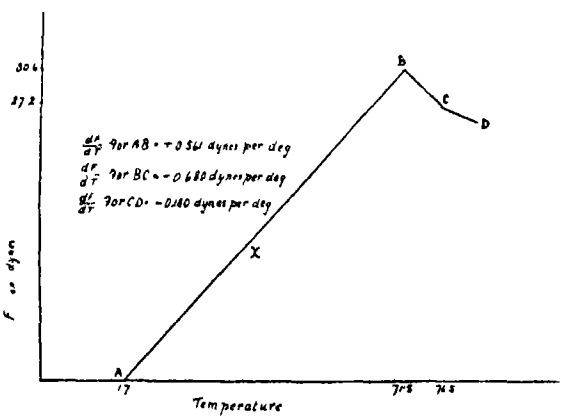

FIG 1

Fig 1 represents a typical F T. curve for stearic acid, in which this equilibrium two-dimensional pressure in dynes per cm is plotted as a function of the temperature

Along the line AB the film in equilibrium with the solid crystal is condensed, the superficial melting-point of the film being at x. At B the crystal melts, and the curve BC represents the variation with the temperature of the condensed film in equilibrium with a lens of the liquid acid At the third non-variant point C the condensed film expands, and the curve CD represents the temperature variation of the two-dimensional expanded film in equilibrium with the liquid lens

As in the case of three-dimensional phase equilibria, it is possible to calculate the various latent heats associated with the changes of the bulk solid and liquid into the two-dimensional condensed and expanded modifications. We may apply a modified equation of the type suggested by Clapeyron,

$$\frac{dF}{dT} = \frac{L}{T(A_2 - A_1)},$$

where A_2 is the area of the film, A_1 the area of the acid in bulk, T the temperature, and L the latent heat of the change in question. From the curve AB we obtain 5860 calories as the latent heat of transformation of the acid from the bulk solid to the condensed film, at the point B From BC we obtain −6840 calories as the latent heat of change of the bulk liquid into the condensed film at the point B. From these two values we obtain 12,700 calories as the latent heat of fusion of stearic acid, a value in reasonably good agreement with 13,500 cited in Landolt Bornstein

In a similar manner, the other latent heats of transformation may readily be calculated, although the actual area of the molecules in the expanded state cannot be computed so accurately as for condensed films

Through the kindness of Mr N. K Adam and Dr. Garner a number of organic acids and esters in a highly purified state have been placed at our disposal, and we have succeeded in obtaining a number of these F T curves and in making similar calculations from the data so obtained We hope to publish these data *in extenso* in the near future, as soon as certain corrections necessitated by the use of the ring method have been accurately determined

Ectodermal Muscles in a Crustacean.

THE generally accepted view as to the origin of the musculature of the Crustacea is that it is derived from the mesoderm In Chirocephalus, while the majority of the muscles arise from the mesoderm, there are others that are definitely of ectodermal origin The dilator muscles of the proctodæum are examples of this type, and probably with these should be classed the dilator muscles of the œsophagus. At the most posterior tip of the body, where the ectoderm folds inwards to form the proctodæal tube, the formation of the dilator muscles can be seen most clearly. Certain ectodermal cells in this region elongate and then, while retaining one end in the outer ectoderm, the other passes inwards with the invaginating ectoderm This passage inwards is probably not an active migration, but is brought about by the proliferation of the surrounding cells, the latter pushing in between the two ends of the muscle cell. In the elongating cell body one or two fibrils appear that very early divide into segments, giving the typical structure of striped muscle. The final muscle is thus an elongated cell, attached at its inner end directly to the cuticle lining the proctodæum and at the other end to the external cuticle.

A more interesting set of ectodermal muscles is to be found in the trunk region. In this region the limbs appear at first as a series of pouch-like outgrowths and, as a result of this development, the ectoderm in between them forms a series of ventro-lateral ridges projecting into the body cavity. As the limb rudiments enlarge, the inner edges of these ridges become nipped off from the more lateral ectoderm. In this way a string of cells is formed on either side in each intersegmental plane, running from the mid-ventral line to the dorso-lateral ectoderm. Deeply staining fibrils appear in them

almost at once. These spread out dorsally into a fan and, running between the nuclei of the superficial ectodermal cells, end directly against the cuticle Ventrally they terminate in a narrow bundle against the cuticle of the mid-ventral line For a considerable time no change other than growth takes place, but ultimately, at the dorsal end, at the level of the inner face of the surrounding ectoderm cells, the fibrils lose their staining capacity and become replaced by a tendinous plate Below this plate the fibrils now divide into segments converting the strings of cells into typical striped muscles Above it they persist as a radiating series of "tendo-fibrils," showing no signs of segmentation and ending directly against the cuticle

On the outer side of this series is another set of muscles having the same median ventral attachment, but having an upper attachment just below—that is, more lateral to that of the first series. These are also entirely ectodermal in origin, and are formed in the same way as the first series

The important facts that emerge from this development are, first, that certain muscles of the Crustacea are definitely ectodermal in origin, a fact not at all in conflict with what might be deduced from the ancestry of the group; and, secondly, that the "tendo-fibrils" that run from the cuticle through the ectoderm cells to attach to endoskeletal structures may be the remains of the same originally continuous fibrils that divide up elsewhere to give the myofibrils of typical striped muscle

On the Absorption Spectrum of Aluminium.

It is well known that the study of the absorption spectrum of elements provides us with the simplest method of determining the normal states of atoms In the hands of Wood, Bevan, McLennan, and others, the study of the absorption spectrum corroborated that in the case of elements of the first and the second groups, the normal orbits are those designated spectroscopically as 1*s* and 1*S* respectively

In the case of elements of higher groups, the experiments become more difficult, as most of them have high boiling-points, so that with the furnaces which can be commanded in a physical laboratory, very little vapour can be obtained for absorption work This difficulty becomes more acute in the case of metals of the third group, all of which, excepting thallium, yield very little vapour up to temperatures of 1200° C.; and, in fact, we are not aware that any successful experiment has been done on the absorption spectrum of aluminium and boron, which are the least volatile elements of this group. At the same time, such experiments are necessary for determining once for all whether for these elements the $2p_1$ orbit is the normal stage, as has been obtained from the analysis of their arc spectra and corroborated by the absorption experiments in the case of indium, gallium, and thallium.

We have recently carried out successfully the absorption experiment with aluminium, using the vacuum furnace designed by Prof Meghnad Saha for ionisation work. The furnace consists of an Acheson graphite tube heated by a battery of accumulators. The temperature was simultaneously measured by a Wanner pyrometer. We used a cadmium spark, and a copper spark under water as our sources of continuous light. The spectrum was photographed on Ilford ordinary plates sensitised by nujol, as described by Lyman. We found that no aluminium lines are obtained below 1500° C. At 1520° C., the pair $\lambda = 3961, 3944$ come out reversed. At 1650° C., the leading members of $2p_t - md$ series come out reversed. The higher members of $2p_t - ms$ series require a little higher temperature Another curious feature is that on all plates the $2p_t - ms$ lines and $2p - md$ lines of gallium occur rather prominently Apparently gallium occurs as an impurity in ordinary samples of aluminium.

From such experiments it is not possible to deduce whether for aluminium the $2p$- orbits are the normal orbits, or whether there is a still larger 1*s* orbit For at the temperature at which sufficient vapour is available for absorption work, the thermal stimulus is quite sufficient to convert any lower 1*s* orbit to the $2p$-orbits The vapour pressure of aluminium is evidently very low even at 1520° C., but we could not find any existing data on the subject, except some theoretical considerations by Gruneisen. Our apparatus is suited to the determination of vapour pressure of aluminium over a large range of temperature by using the so-called *Mitfuhrungs-methode* of Pfaundler, and we hope to carry it out at an early date At any rate, it is quite clear that the $2p - mx$ lines require a lot of vapour for absorption, and if the $2p$- orbits turn out to be the normal orbits of aluminium atom, they do not dominate the spectrum to the same extent as the 1*s* orbits of alkalies dominate their spectra

The Origin of Sponge-spicules.

It is to be regretted that Dr Bidder (NATURE, February 28), before publishing his criticisms of my theory of the symbiotic origin of sponge-spicules, did not await the publication of the detailed evidence upon which that theory is based I am loth to enter into controversy with him, but as his letter contains much that is misleading, I feel that I can scarcely pass it over in silence He speaks of the observation (presumably mine) "that the first rudiment of the spicule in Stelletta is a skeleton-crystal on the tetrahedral system" I made no such observation On the contrary, I endeavoured to show by observations on the silica pearls that the first rudiment is a minute granule resembling a Micrococcus

Dr Bidder's "crystallographic explanation," so far as siliceous sponges are concerned, appears to rest on the assumption that the protorhabd, or axial thread, is itself composed of silica Otherwise it would be difficult to understand his "conjecture" as to the variation of the type of crystallisation with the percentage of water in the "spicopal." His supposed "skeleton-crystal" can be nothing but the radiating axial threads He admits that the silica afterwards deposited upon it is "in amorphous aggregation" Unfortunately, the best observers, such as Bütschli and Schulze, are in agreement that the axial thread is composed of a protein substance, and there is nothing else that could form the siliceous skeleton-crystal which he imagines to exist The statement that my scleroplastids "are at first gelatinous but become crystalline" is pure invention. It is well known that the axial thread, formed, as I believe, by elongation of the scleroplastid, retains its original "organic" character in the axial canal of the fully formed spicule, and, so far as I am aware, no one has hitherto ventured to suggest that it becomes crystalline.

Dr Bidder accuses me of having "strangely changed" the name of a certain sponge to Donatia. If he will study the literature of the subject he will

find that this is the name now generally given by spongologists to the genus in question, and for very good reasons I have merely followed precedent, and in any case I fail to see what the nomenclature of this genus has to do with the question at issue

What Dr Bidder means by saying that the Suberitidæ have triaxon spicules I do not know I can only say that Suberites has not In his reference to the "innumerable 'species' of sponges which infest our books," he seems anxious to belittle the work of "classifiers," but if he would pay more attention to this work he might perhaps come to realise that it has plainly demonstrated that sponge-spicules, like other organic products, have a long evolutionary history behind them, that they can be arranged in evolutionary series, and that in their individual development they may actually recapitulate their ancestral history. It is perfectly useless for any one to attempt to discuss this subject merely on the basis of acquaintance with a few of the simpler spicule forms.

The Action of Silica on Electrolytes.

THE questions raised in Prof Mukherjee's letter of January 31 are so important that I should like to reply briefly

(1) I have not found any reason to depart from the views expressed in our paper in the Transactions of the Chemical Society (T. 1923, 123, 2027) that pure silica does not exhibit any absorbing or reacting power towards acids I have made experiments with commercial "silica gel" and N/500 hydrochloric acid, and at first obtained an indication of absorption, but soon found that this was due to some impurity, as the specific resistance of distilled water was lowered from 500,000 to 35,000 ohms on addition of the gel. It was therefore purified by washing once with hydrochloric acid and then repeatedly with water until the specific resistance rose to 350,000 ohms, and finally dried and heated to 180° After this treatment, no absorption of acid could be observed, the P_H of the acid being the same (2 69) before and after the addition of 10 per cent of the gel An experiment with oxalic acid, using gel which had been purified with nitric acid, also gave a negative result.

(2) It is not clear how previous treatment with acid can destroy any absorbing properties that silica possesses, and I presume that Prof Mukherjee's hydrated substance comes in contact with acid at some stage of its preparation. However, to make sure, the gel purified with hydrochloric acid was fused with sodium carbonate and the residue tested with silver nitrate, no chloride could be detected

(3) I do not quite see Prof Mukherjee's difficulty in understanding the experiment in which we found that, whilst pure silica reduced the P_H of sodium chloride solution to 3 96, the impure silica (which contained alkali) only did so to 5·55 The concentration of the silica suspension used was 20 grams per litre, and it seems quite reasonable that 20 grams of an impure alkaline material should neutralise 10^{-4} grams of hydrogen-ions

(4) In this connexion I may point out that the hydrogen-ion concentration of a weak acid solution (*e.g* N/5000 hydrochloric acid) falls to about half its calculated value when left for a few minutes in an ordinary glass vessel. No change is observed if the vessel is coated internally with paraffin wax or is made of silica. Filter papers also must be used with caution, as all those tried change the specific resistance and P_H of distilled water.

This problem is of great interest to us, and if Prof. Mukherjee could at any time spare a small quantity of his pure hydrated silica, we should very much like to make experiments with it A. F. JOSEPH.

The Reported Anti-Relativity Experiment.

UNFORTUNATELY, owing to travelling delays, a modified proof of my response to an editorial inquiry (appearing in NATURE of March 21, p 433, col 1) did not reach the printers in time The experiment reported as having been attempted by Prof Michelson and Dr Silberstein can scarcely have been conducted in water, though water-pipes were used It may probably be conveniently regarded as a large-scale reproduction of an experiment by an Italian professor who inverted my whirling disk experiment on ether (Phil. Trans., 1893) by mounting the whole of the apparatus on a turn-table, including source of light and receiving camera, and looking for a shift of interference bands photographically In the experiment now reported the turn-table was apparently replaced by the earth I suggested such an experiment on p 151, vol 189, of the Phil Trans for 1897 If, as is probable, a positive effect can ultimately be securely demonstrated, it will be for relativists to say whether their position is at all affected, or whether the loop-hole—that rotation is exceptional, because in rotation matter is moving oppositely on opposite sides of the axis—is acceptable

It may be convenient to reproduce the passage from Phil Trans., 1897, referred to above

"It is to be observed that since a motion of the disks relatively to the observer and the light causes no effect, the ether being stationary, it follows that a motion of the light and observer would produce an effect, since they would be moving relatively to the ether. Hence if, instead of spinning only the disks, the whole apparatus, lantern, optical frame, telescope, observer and all were mounted on a turn-table and caused to rotate, a reversible shift of the bands should be seen . . My present optical apparatus mounted on a turn-table revolving 4 times a minute should show something, viz., $\frac{1}{10}$th band shift each way . . . If the ether is stationary near the earth, that is, if it be neither carried round nor along by that body, then a single interference square, 1 kilometre in the side, would show a shift of rather more than one band width, due to the earth's rotation in these latitudes (see p 772, Phil. Trans., 1893)

"But as the effect depends on the area of the square, a size of frame capable of mechanical inversion is altogether too small, there may, however, be some indirect ingenious way of virtually accomplishing a reversal of rotation—something, for instance, based on an interchange of source and eye—and if so, it would constitute the easiest plan of examining into the question of terrestrial ether drift"

OLIVER LODGE.

The Glow of Phosphorus.

THE process of the slow luminous oxidation of phosphorus presents anomalies which are still incompletely understood. Thus, the non-occurrence of a glow in pure oxygen until the pressure is reduced to about 500 mm. of mercury, or an equivalent dilution with an inert gas is made, is very striking. No less difficult to explain is the ability of traces of certain vapours to inhibit the luminosity. These

features are also exhibited in the slow oxidation of phosphorus trioxide, and it has been suggested that the phenomena of the glow of phosphorus are due to the trioxide formed in a preliminary non-luminous oxidation. Again, phosphine does not react with oxygen at ordinary pressures, but on reducing the pressure an explosion occurs.

With the view of elucidating these difficulties the nature of the light emitted in these oxidations is being studied spectroscopically. It was recently shown (Emeléus and Downey, J.C.S. Trans. 125, 2491, 1924) that the light from glowing phosphorus, and that from the element burning normally, give the same spectrum. This is continuous in the visible region, and has five bands in the ultra-violet between $\lambda = 2370$ Å.U. and $\lambda = 3290$ Å.U. These observations have now been extended with the following results: the light from glowing phosphorus trioxide, and from spontaneously inflammable phosphine burning in oxygen, give this same spectrum. In the first case the strongest three of the five ultra-violet bands have already been identified. There is little doubt that the remaining bands will be shown on lengthening the exposure. In the second case all five bands have been observed, in addition to bands generally attributed to water at about $\lambda = 3060$ Å.U. and $\lambda = 2800$ Å.U.

The fact that the light from glowing phosphorus and that from phosphorus trioxide both give the same spectrum supports the analogy between these two oxidations, already well established in other respects. These observations, however, cannot be taken as proof of the identity of the chemical processes. They indicate rather that there is some radiating system involved in them all, which gives rise to a definite band spectrum. Such a system may well have a connexion with the chemical anomalies common to the low temperature oxidation of these phosphorus compounds.

The Structure of the Mercury Line 2536.

AN investigation of the fine structure of the 2536 line of mercury has just been completed as a preliminary to the continuation of the work on the controlled orbital transfers of electrons in optically excited mercury vapour described recently in the Proceedings of the Royal Society. It has been found that the structure photographed by Prof. Nagaoka is not the true structure at all, but an absorption spectrum, or perhaps more exactly a structure caused by the self reversal of the true components, resulting from the circumstance that he worked with an Arons-Lummer type of lamp, in which the light of the arc is obliged to pass out through a column of non-luminous mercury vapour, before entering the interference spectroscope.

The true structure has been observed with a water-cooled vertical quartz mercury arc, the discharge being pressed against the wall of the tube adjacent to the spectroscopic train by a very weak magnetic field. There are five components of uniform intensity, four at sensibly equal intervals, the fifth having a slightly greater separation. The observations were made by two quartz Lummer-Gehrke plates crossed in the usual manner. On passing the light through a cell 1 cm. in thickness containing mercury vapour in vacuo at room temperature, each one of the interference points doubles by reversal and we have a row of ten dots. On increasing the thickness of the absorbing layer some of these coalesce, and we end up with a structure sensibly the same as that described and figured by Nagaoka: I say "sensibly" as there appears to be a slight difference between the absorption of mercury vapour in a separate cell, and that of the vapour in the neck of the Arons lamp, which is in a state of ionisation from its contact with the arc. The effect of magnetic fields on the components has also been studied.

Les rayons γ de haute énergie et leur effet photoélectrique.

DANS une lettre récente à la NATURE (Feb. 14, p. 226) Mr. D. H. Black attire l'attention sur un rayon γ du thorium B d'énergie élevée. Son interprétation dans le spectre naturel indique sa conversion en rayon β par son action sur les niveaux *K* et *L* d'un élément de nombre atomique 82 ou 83.

Ces faits sont à rapprocher de ceux que M. Jean Thibaud a signalés il y a quelque temps (*Comptes rendus*, tome 178, 1924, p. 1706; tome 179, 1924, pp. 165, 815, 1052, 1322). M. Thibaud travaillant dans mon laboratoire a pu obtenir les spectres excités photoélectriquement par des rayons γ dans les éléments les plus divers; il a montré qu'on observait la conversion de rayons γ de près de deux millions de volts sur les niveaux *K* et *L* d'atomes lourds (uranium, plomb, platine, tungstène). En particulier un rayon γ de 1,775,000 volts, émis par le radium C, se convertit sur des niveaux *L*, d'énergie *140 fois moindre*.

L'effet photoélectrique des rayons γ de haute énergie se produit avec une intensité remarquable sur les niveaux *K* d'éléments plus légers, tels que le cerium, l'antimoine, l'étain, l'argent et même le cuivre et le fer.

M. Jean Thibaud a vérifié très exactement, en étudiant le déplacement des diverses raies photoélectriques lorsque l'on fait varier le nombre atomique du "radiateur" secondaire, que la relation quantique d'Einstein était aussi bien valable pour les quanta très élevés que pour les plus faibles. Il a montré enfin l'identité des spectres β naturels et des spectres β excités pour Ra B+C, Th B+C+C″, Ms Th 2 et confirmé ainsi l'origine secondaire des spectres naturels de ces éléments.

Radio Reception on Frame Aerials.

I WAS much interested in Mr. Cowper's letter in NATURE of February 21 on radio reception on frame aerials. For some time I have been quite sure that the usual estimates of probable signal strengths are much too low.

On a four-valve (1 H.F. Det. 2 L.F.) it is possible, on a roughly constructed frame 16 inches square, of 30 D.C.C., to receive all B.B.C. stations at loud-speaker strength. The tuning is very acute, and, as Mr. Cowper mentions, with special arrangements for reaction control. This was with B.T.H. B.5 (0·06) valves. I have never tried for American stations, but have no doubt they could be heard.

The station was on the south side of a sheltered valley and the apparatus about 6-8 ft. above the ground. The first station I ever heard was Manchester, so loudly that, until the announcer gave the name, I was quite sure it was either Plymouth, 25 miles, or Bournemouth, 90 miles, distant.

The Rotor Ship and Aeronautics.

By Prof. L. BAIRSTOW, F.R.S.

THE conversion by Herr Anton Flettner of the sailing ship *Buckau* into a rotor ship was referred to in NATURE of November 22, p. 758, and brief reference was then made to the principles underlying the new proposal for ship propulsion. Since then, details of experiments in wind channels have appeared from which estimates may be made of the forces on rotating cylinders and the power needed to drive them.

Experiments at Göttingen, and the underlying theory, are described by Prof. L. Prandtl in *Die Naturwissenschaften* for February 6, whilst the same material is the basis of a small booklet, "Das Rotorschiff und seine physikalischen Grundlagen," by J. Ackeret.[1] Both these publications contain a bibliography, the earliest reference being to a paper by B. Robins in 1842 (London) Owing to the importance of his investigations, the effect on which the rotor ship depends is spoken of as the "Magnus effect," and is described in a paper published in 1852 in connexion with artillery investigations. Lord Rayleigh's paper of 1877 "on the irregular flight of a tennis ball" deals with the same mathematical theory. Tests for the American National Advisory Committee for Aeronautics have been made and the results published in Technical Note No. 209, a very full abstract of which appears in the issue of *Flight* for January 8, 1925.

The analysis underlying the use of rotating cylinders for rotor ships is the classical hydrodynamical theory to be found in standard treatises.[2] In the application, certain approximations are made and there is some lack of agreement between calculation and observation corresponding with them. The most important assumption is that which supposes the effects of viscosity in a real fluid to be confined to a thin layer on the surface of the cylinder and that, outside this boundary layer, air behaves as an inviscid fluid. The general theory of the boundary layer as given by Prandtl shows it to be thinner and thinner as the speed and size increase and as the viscosity decreases. The exact criterion is a "Reynold's number." For a non-rotating cylinder this "Reynold's" number is Vr/ν, where V is the forward speed of the cylinder, r its radius, and ν the kinematic coefficient of viscosity. When the cylinder is rotating with a circumferential velocity U there will be a separate "Reynold's number" for each value of the ratio U/V.

Any one acquainted with the flow of air or water past bluff obstacles will be aware of the fact that eddies form in their wake and that there is a region of stagnant fluid which does not conform to the hypothesis that the boundary layer is thin, and in fact the classical hydrodynamics is wholly inapplicable to a non-rotary cylinder. The streamlines as calculated are shown in Fig. 1, and give a motion for which there is no force on the cylinder in any direction. The flow round a cylinder in a real fluid differs very greatly from that shown behind the section BB'.

Rotation of a cylinder in stationary fluid produces circulation. Viscosity is called into play to ensure the transmission of the motion of the cylinder to the fluid in contact with it, but in all other respects viscosity is ignored. The resulting streamlines are circles concentric with the cylinder, the velocity in them being inversely proportional to the distance from the centre of the circle.

By superposition on the well-known lines of Clerk

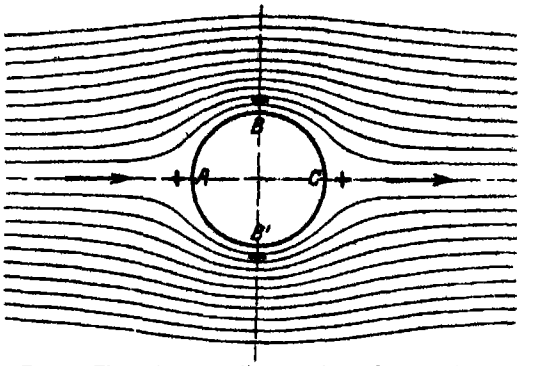

FIG. 1.—Theoretical streamlines round a stationary cylinder. Reproduced by courtesy of *Die Naturwissenschaften*.

Maxwell and others, it is easy to combine the flow shown in Fig. 1 with a circulation of any amount, and the result is shown in Fig. 2. The circulation has produced lack of symmetry above and below a horizontal line through the centre of the cylinder, but has not disturbed symmetry about the line BB'. By an application of Bernoulli's theorem it may be deduced that there is a force along BB' but none at right angles

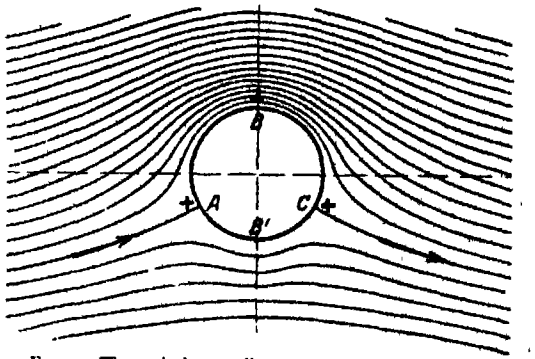

FIG. 2.—Theoretical streamlines round a rotating cylinder. Reproduced by courtesy of *Die Naturwissenschaften*.

to it. Bernoulli's theorem as applied to an inviscid fluid gives a relation between pressure, velocity, and density, which shows that high velocity is associated with low pressure, and vice versa. Above the cylinder, at B, the streamlines are close together, and since the same amount of fluid passes between any two consecutive lines, the velocity is high and the pressure low. Similarly the pressure at B' is high.

The general theory of inviscid flow with circulation leads to the formula

Lift = Force across the direction of motion = $\rho V \Gamma$ per unit length,

where ρ is the density of the fluid, V, U, and r have

[1] "Das Rotorschiff und seine physikalischen Grundlagen." Von J. Ackeret. Pp 48+7 Tafeln (Göttingen Vandenhoeck und Ruprecht, 1925.) 1·80 gold marks.
[2] "Hydrodynamics," Lamb, Articles 68 and 69.

already been defined, and l is the length of the cylinder. Strictly speaking, l should be the length of that part of an infinite cylinder on which the force is measured, but it appears from experiment that a cylinder of moderate ratio of length to diameter can be used if discs of double diameter are attached to the ends; a circulation is then obtained which is equivalent to that on a cylinder of indefinite length.

As the speed of rotation increases, the streamlines change their character progressively up to a limit. When the circumferential velocity is twice the velocity, a limit is reached to the value of the lift divided by ρUV, and in aeronautical language this leads to a limiting value of the lift coefficient defined as

$$\text{Lift coeff., } i.e.\ k_L = \frac{\text{Lift}}{\rho V^2 \times \text{projected area of cylinder}}.$$

This limit, or maximum lift coefficient, is 2π. The quantity is important, because the loading of an aeroplane per unit area of surface at a given speed is proportional to k_L or, conversely, for a given loading the landing speed is inversely proportional to the square root of k_L (max.).

The more efficient aeroplane wings of the day have a maximum lift coefficient of about 0·6 and may reach 0·85; by introducing a number of slots Mr. Handley Page has obtained the highest values known, about 2·0. From figures at Göttingen given by Ackeret, it appears that the maximum lift coefficient for a sail is about 0·4. All these values are much below the theoretical value of 2π, *i.e.* 6·28. Making allowance for partial failure of the theory, it still remains true that the loading per unit area of a rotor cylinder may be ten times as great as that on a sail and several times as great as that on any aeroplane wing in use.

It may be of interest to point out the existence of a conformal transformation by Joukowsky by means of which the circle of Fig. 2 can be transformed into a section very like that of an aeroplane wing. Experiments at the National Physical Laboratory have shown that such a transformation gives a passable representation of facts but that the lift is overestimated by 25-30 per cent. A circulation has been shown to exist of exactly the right amount to explain the measured—as distinct from the calculated—lift. An aeroplane wing, therefore, is able to produce circulation without any movement of its surface corresponding with the rotation of the cylinder. The transformation is important in its aeronautical aspects, but the numerous points of interest which arise cannot be further discussed here.

It is interesting to see how far the predictions of this partial theory are borne out in practice. In some respects there is a considerable divergence between German and American results, and a suspicion that the experiments in the wind channels have not yet been carried out on a scale large enough to reach limiting conditions. The doubts chiefly affect the resistance.

In the American tests, smoke jets were used to indicate the flow of air, and Fig. 3 shows how rotation of the cylinder (clockwise) deflects the air. The symmetry about a vertical line through the centre of the cylinder is not perfect, and the streamlines suggest resistance as well as lift. The extent to which air is carried to the back of the cylinder at the higher speeds of rotation is a notable feature shown by the photographs.

Measurements of lift showed a maximum lift coefficient of 4·5 (theoretical value 6·28) when the peripheral speed was about four times the forward speed. Instead of the maximum value of 6·28 when the peripheral speed was twice the forward speed, observation gave a value of 2·0. These comparisons show to what extent the neglect of viscosity in the theory has vitiated the conclusions.

It will be noticed that high speeds are required at the surface of the cylinder to give the maximum effect.

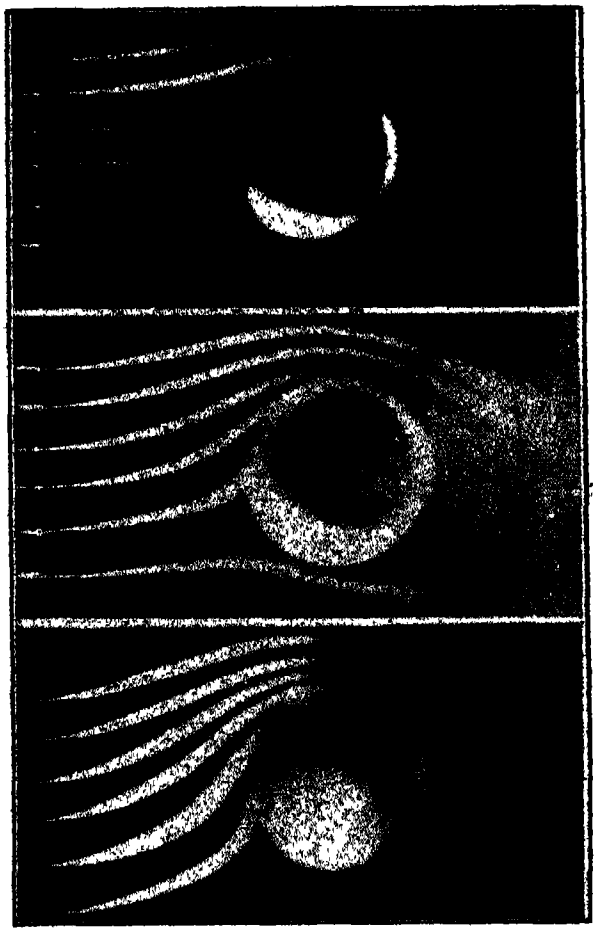

FIG. 3.—Deflexion of air stream by rotating cylinders: top, 600 rev. per min., middle, 1200 rev. per min., bottom, 2400 rev. per min. Reproduced by courtesy of *Flight*.

Regarded as an aeroplane wing, such high speed would be required at the moment of landing, and if an alighting speed of 30 m.p.h. is aimed at, the surface of the cylinders would need to move at 120 m.p.h. For transport efficiency when once in the air, the factor of greatest importance is the ratio of lift to drag, and on a rotating cylinder this is obtained when the peripheral speed is about two and a half times as great as the forward speed. Whilst the Göttingen results give a maximum ratio of 3·5, the American figures give 7·5-8, and the discrepancy is very great. The figures are subject to a deduction for the power required to rotate the cylinders, a deduction of rather uncertain amount but of the order of a quarter to a third of the

values stated. The modern aeroplane has a ratio of lift to drag of 9, and some of the light aeroplanes indicate a figure as high as 12 or 14, so that the best of the results on rotating cylinders compare very unfavourably with the aeroplane for efficiency.

Whatever may be the final utility of the rotating cylinder and the commercial fate of the *Buckau*, it may be expected that many attempts will be made to utilise the aspect of fluid motion brought into new prominence by the rotor ship. Whilst it is difficult to see immediate uses in aeronautics, there are certain directions in which speculation suggests the possibility of early benefit by a modified application of the principles involved in the propulsion of the rotor ship.

The Mountain Structure and Geographical Relations of South-Eastern Asia.[1]

By Prof. J. W. Gregory, F.R.S.

THE greatest mountain system in the world is the Alpine-Himalayan, which forms the backbone of Europe and Asia. Its continuity has been proved from western Europe to eastern India. Its further eastward continuation has long been subject of controversy. According to one view it passed northeastward across central China to Bering Straits; according to another it was bent round against the mass of Chinese Tibet, and passed through western Burma to Sumatra and thence along the southern islands of the Eastern Archipelago. The interpretation of the mountain structure of Chinese Tibet is complicated by being due to movements at two different dates. The later mountains are of the same age as the Alps and Himalaya and are geologically modern. The other group is much older, and its fragments remain as highlands, which are the worn down stumps of the mountain foundations. The older system is represented in Europe by the Hercynian Mountains, and in Asia by the Altaids, members of which cross Chinese Tibet on lines approximately north and south, and continue southward as the Indo-Malayan Mountains. The Himalayan and Altaid Mountains meet in Chinese Tibet, and the mountain lines due to these two systems have to be carefully distinguished. The Himalayan movements have disturbed the grain due to the older Altaid folding and they admit of simplest proof where the rocks were not in existence when the Altaid Mountains were made. For example, the folds and overfolds in the salt-bearing red sandstones of Yunnan must be post-Altaid, as those rocks were not in existence until after the Altaid movements. In other places the evidence is more complex. Some of the folds are too shallow to be Altaid, and the arrangement of the outcrop of the older rocks indicates upfolds on lines with the Himalayan trend.

The further extension of the Himalayan line eastward of Chinese Tibet is indicated by the claim of the French geologists in Tonkin that at the date of the Himalayan movements a band of country in southern China was pushed southward smashing the country in front of it. The existence of a rich mercury field in south-western China is also in favour of the country having been disturbed by intense mountain movements of the Himalayan period. The continuation of the main Alpine-Himalayan axis therefore appears to pass across southern China, and the Burmese-Malayan Arcs must belong to a loop to the south corresponding to the Atlas-Apennine loop around the western Mediterranean and the Syrian Arc beside the eastern Mediterranean.

[1] From a discourse delivered at the Royal Institution on Friday, January 30.

The traditional cause assigned to such folding as that of the Alps and Himalaya is the contraction of the crust owing to the shrinkage of the earth. That theory has been repeatedly criticised in recent years owing to the contraction having been attributed to cooling; but there are more effective and more probable causes of contraction than cooling. That contraction has taken place is proved by the geological evidence. The restriction of the Alpine-Himalayan compression to a long narrow band, varying in latitude from 40° to 48° in Europe, and from 25° to 38° in Asia, is the natural result of that sinking of the northern dome of the world which is shown by the polar flattening. The junction of the northern dome with the tropical belt is naturally one of crumpling and crustal disturbance. This process would produce uplifts in the same zone of the crust around the northern hemisphere, and traces of this continuous upheaval are found. The West Indies and Central America include fragments of mountain chains formed at the same time as the Alps and with a similar trend

The abrupt ending of the mountain grain of the continents on both sides of the Atlantic indicates the former extension of the land into the ocean. That the land once crossed the whole width of the Atlantic is supported by the biological evidence. Similar animals are found on opposite sides of the Atlantic in corresponding latitudes, and the resemblances of the South American and African faunas are not likely to be due to passage via Scotland and Greenland if there are no representatives of those groups in Europe or North America. The distribution of the ridges and deeps on the North Atlantic floor indicates uplifts in North America and western Europe at the time of the Alpine movements. There is similar evidence of former land extensions across the northern and southern Pacific, such as the occurrence of the alligator in the Yangtze Kiang, the resemblance of the flora of southern China to that of the south-eastern United States, and the occurrence on both sides of the South Pacific of various groups which are unrepresented in the lands on either side of the North Pacific. The biological evidence is supported by the ridges on the Pacific floor and the distribution of the coral islands. The former trans-Atlantic and trans-Pacific connexions must have endured until the time of the Alpine-Himalayan uplifts, for they were broken before the spread of the more specialised mammals and birds, and were available to some living groups of reptiles, amphibians, and specialised invertebrates.

The Indian Ocean was also once occupied by land, the disruption of which has affected the mountain structure of south-eastern Asia. At the end of the

Altaid uplifts the site of the Indian Ocean was covered by a continent which extended from South America across the Old World to Australia. This continent, Gondwanaland, was broken up by successive subsidences; and the gulfs thus formed were gradually enlarged by further subsidences and so developed into the Atlantic and two basins of the Indian Ocean. These movements were accompanied by volcanic eruptions which deluged equatorial Africa and western India under floods of lava, while East Africa was torn asunder by the formation of the Great Rift Valley. If these eruptions and fractures were due to the formation of the Indian Ocean, it appeared strange that no corresponding phenomena were known on its eastern side. The evidence, however, is now clear that in Burma and western China there were volcanic eruptions which, though on a smaller scale, agree in date with the three main volcanic periods of East Africa; while meridional fractures of the same date as those which made the Great Rift Valley formed the great basins of Yunnan in western China. These fractures in Asia produced features different in some respects from those of East Africa, owing to the difference in structure between the continents. East Africa is an ancient solid plateau, whereas Yunnan has an extremely complex foundation due to the intersecting mountain folds. The fractures have therefore been less regular and shorter.

The date of the later movements in Chinese Tibet is indicated by the river system. The drainage of south-eastern Tibet collects into three rivers which flow for 140 miles on parallel courses through a narrow belt, and instead of joining they then diverge, the Yangtze discharging into the China Sea 2000 miles from the mouth of its neighbour, the Salween The present river system is the result of a long evolution controlled by the mountain-forming movements. The drainage of central and south-eastern Asia in pre-Himalayan times was probably mainly through broad east to west trending valleys due to a gentle buckling of the earth's crust. The Himalayan movements confirmed this system; but during the subsequent settling down of the country the eastward outlet of the Tibetan rivers was reduced and Tibet became a land of lakes, to an extent even greater than it is now. Their level rose until they found outlets to the south, through lines of weakness along the Altaid grain. The Tibetan rivers through these southern outlets discharged to the South China Sea. The upper Brahmaputra or Tsangpo discharged through the Dihang, crossed the site of Assam, and passed through the Hukong Gap to the Irrawadi. The Tibetan section of the Yangtze Kiang flowed through Tali Lake to the Red River of Tonkin. Further earth movements broke up this system and diverted its western member through the valley of Assam as the Lower Brahmaputra to the Bay of Bengal, and the eastern by a series of deep gorges and striking zigzags across eastern China to the South Pacific.

The geographical relations of the mountains of south-eastern Asia therefore indicate that the Alpine-Himalayan System is a crumpled band of the crust, where the in-sinking northern dome of the world pressed against the tropical belt. The east to west ridges on the floors of the North Atlantic and North Pacific may be attributed to the same forces as produced the Alps and the Himalaya; and the east to west trending mountains, of which remnants are the dominant features in the topography of the West Indies and central America, are also an expression of the buckling of the crust of the Northern Hemisphere where the northern dome of the earth meets its tropical and subtropical belt.

Recent Developments in the Nitrogen-fixation Industry.

WHEN the historian of the future writes concerning the influence of scientific discovery and achievement upon civilisation, we may be sure that he will have much to say about the political and economic effects of the development of the nitrogen-fixation industry. Of all the material factors that helped to make the War the greatest and most devastating conflict in human history, the possession by the Germans of adequate plant for making synthetic ammonia, and of adequate personnel for working it, was probably the most important. Since that time the processes for fixing atmospheric nitrogen have been further developed, and the present yearly production of fixed nitrogen is approximately 500,000 metric tons, three-quarters of which is made in Germany.

The arc process, the lineal descendant of Cavendish's initial discovery in 1783, now contributes only a relatively small proportion of the total production, namely, about 36,000 m.t., its high power-requirement rendering it uneconomical save in countries possessing cheap and abundant water-power. The modification of the process involving the use of oxygen-enriched air, which was worked principally in Switzerland and Germany until 1921, had to be abandoned owing to the serious explosions to which it gave rise. The Swiss Nitrum Co., which worked it on a large scale, has recently adopted the Claude process in its stead.

Fixation by means of calcium carbide was developed enormously during the War, but the present outlook for this method is not promising: calcium cyanamide has not come up to expectations as a nitrogenous fertiliser, and the power-requirement, although only about one-fifth that of the arc process, is 3-4 times greater than that of the direct synthetic-ammonia process. The output of cyanamide has declined to about 140,000 m.t. per annum, and about one-half of the world's plant capacity is unutilised. There are, however, still possibilities, for cyanamide can be used as an intermediate product in the manufacture of urea, of ammonia, and of "Ammo-phos," a fertiliser made on a small scale in the United States.

Urea appears to be the nitrogenous fertiliser of the future. It is the most concentrated of its class; it can be transported and used without difficulty; it leaves neither acid nor alkali behind in the soil; and it has given general satisfaction in experimental work. It will probably be manufactured by combining synthetic ammonia and carbon dioxide at high temperature and pressure. Since 1922 a combination of urea and acid phosphate, called "Phosphazote," has been made in Switzerland, and a large works in Norway is to start its production early in the current year.

The Haber process and its modifications, involving the direct union of nitrogen (from liquid air) and

hydrogen in presence of a catalyst, at various temperatures and pressures, now contribute about 65 per cent. of the world's supply of fixed nitrogen. In this process the cost of producing and purifying the hydrogen is a dominating factor; in Germany it is prepared from water-gas (Bosch process), in France by fractionating coke-oven gas (Claude process), and in Italy by electrolysing water (Casale and Fausser processes). Electrolytic hydrogen is very pure, but its production is only feasible where water-power is cheap. The Casale process is being actively worked in Calabria by a company with a capital of 9 million Swiss francs, and in the United States the Hooker Chemical Co. is so satisfied with its success that it has decided to double its plant at Niagara Falls.

Other important factors in the Haber process are the choice of catalysts and the form of marketing the ammonia. In the Fixed-Nitrogen Research Laboratory of the United States Government, improved catalysts have been made which, it is expected, will reduce the cost of ammonia-production by one-half; working on a small scale, at 1500 atmospheres pressure, nearly 80 per cent. of a nitrogen-hydrogen mixture was converted during a single passage through the catalyst. Improved catalysts have also been made for the water-gas reaction ($CO + H_2O = H_2 + CO_2$). With these and other improvements it is hoped to reduce the price of ammonia to 5-6 cents per lb.

At Billingham-on-Tees, Synthetic Ammonia and Nitrates, Ltd., has started manufacture on a large scale. A modified Haber process is used, and the ammonia is fixed by the calcium-sulphate method, which was developed, and is still used, in Germany. It is probable that synthetic ammonia will be used in conjunction with the Solvay soda process, the ammonia being converted into ammonium chloride, which preliminary trials have shown to be comparable with ammonium sulphate in fertilising value.

The Bucher process of fixing nitrogen as cyanide has not fulfilled expectations, but it appears probable that the du Pont Co. will make it a success. Instead of passing nitrogen (at 15 lb. pressure) over soda ash, coke, and a catalyst, this company uses producer-gas and a mixture of carbon black and soda ash (plus catalyst) obtained by evaporating to dryness the "black liquor" which results from boiling wood with caustic soda in the manufacture of wood-pulp, and by heating the residue out of air at 250°-350° C. This mass is very porous, and contains 60-65 per cent. soda ash and 40-35 per cent. carbon, mainly colloidal. The yield of cyanide at this stage is 50-55 per cent., and the period of heating is only 70 per cent. of that required in the original process. The reaction-product is leached with water, and 96-98 per cent. sodium cyanide is obtained by crystallisation. The carbon monoxide evolved during heating is mixed with producer-gas and burned under the retorts, which are made of very resistant cast chrome-iron alloy, high in chromium. A valuable decolorising carbon is extracted from the residue after leaching. Cyanide, it may be mentioned, can be decomposed by steam to yield ammonia.

The marvellous growth of the nitrogen-fixation industry has naturally excited those interested in the production of Chilean nitrate, the consumption of which has not advanced *pari passu* with that of the artificial products; but the processes used in Chile are known to be wasteful, the Chilean Government could reduce the export tax of 50*s.* per ton in case of emergency, and the deposits are likely to last much longer than was originally thought probable. In view, however, of the fact that no other nitrate deposits, in any way comparable with those of Chile, have been discovered, it can only be a question of time—a generation or two—before the synthetic products will hold undisputed sway. It is, of course, possible that means may be found of speeding up nitrification in the soil, but even in that event no nation could afford to be without a nitrogen industry for producing explosives. Furthermore, fixed nitrogen is being increasingly used as ammonia for cold-storage plants, as cyanide for gold extraction, and as nitro-cellulose for making celluloid, artificial leather, and similar products. Great developments of the industry may, therefore, be confidently anticipated.

Obituary.

The Marquess Curzon of Kedleston, K.G., F.R.S.

BY the death of Lord Curzon, Lord President of the Council, and formerly Viceroy of India and Secretary of State for Foreign Affairs, on March 20, public life in Great Britain has lost one of its most striking personalities. His long and distinguished career in politics had won him high honours in the State; but in a more restricted circle he was held in equal esteem for his scholarship and his efforts to promote those studies with which his interests and pursuits had brought him into touch.

George Nathaniel Curzon, son of Lord Scarsdale, was born on January 11, 1859. After a distinguished career at Eton and Oxford, which included the presidential chair of the union and led to a fellowship of All Souls, Mr. Curzon, as he then was, embarked on a political career, entering Parliament in 1887, first holding office as Under-Secretary of State for India in 1891, by which time he was already recognised as an authority on the East. It is unnecessary to enter here into the details of his political career, which are well known. His services to the State were recognised by successive peerages of every grade up to the rank of marquess and the orders of the Garter, the Indian Empire, the Star of India, and the Royal Victorian Order.

Apart from politics, Lord Curzon won distinction as a geographer and student of the peoples of the East. Between 1886 and 1894 he visited India four times and twice travelled round the world. In 1888 he travelled through Asiatic Russia, recording his observations in his book "Russia in Central Asia." He followed this with a book on Persia and the Persians, a comprehensive account and perhaps his most considerable contribution to geographical literature, which later was to have considerable effect on policy in the Middle East and is still a work of authority. This appeared after a journey in Persia as correspondent of the *Times* in 1889, in the course of which he travelled more than 1600 miles on horseback and toured the Persian Gulf. A later book, "Problems of the Far East," dealt with conditions in and the prospects of the countries lying

between India and the Pacific. In 1894 he visited the Ameer of Afghanistan—then an undertaking entailing some considerable risk—after tracing the Oxus to its source in the Pamirs. Behind his preoccupation with races and people as factors in international politics, Lord Curzon had a fund of sound geographical knowledge, and in fact, as was shown by essays in his often amusing "Stories of Travel," published in 1923, he was a scientific geographer of no small attainment. In geography and in the study of peoples, as in his work as an administrator, it was characteristic of him to pursue exhaustive inquiry and to master the available data relating to his subject before arriving at any conclusion on his own observations. The result would then be expressed with a lucidity which reflected his clarity of judgment. His contributions to geographical science were recognised in 1895 by the award of the Royal Geographical Society's gold medal, an honour which he prized highly.

As Viceroy of India Lord Curzon did much to promote science in that country. Apart from his lasting reforms in education and his efforts to improve the conditions of agriculture, both being placed under trained officers, he reorganised the archæological service, which had fallen into neglect, reviving the office of Director-General. In 1904 he passed a Monuments Act, and he saved from profanation and decay innumerable temples, tombs of kings, mosques, and other buildings throughout India, including the native states. Native arts and industries were fostered, and he created the Imperial Library in the Metcalfe Hall and was responsible for the Victoria Memorial on the Maidan, Calcutta, a gallery of Indian art and history. His own researches into the history of his predecessors in the Viceregal office were on the point of publication at the time of his death.

It may be recalled that Lord Curzon and Lord Kitchener were the principal guests of the Royal Society at its anniversary dinner in 1898. Within a few days both were due to leave England to take up their new Indian appointments. In a letter to Lord Lister, the president, a few days prior to the banquet, Lord Curzon wrote: "It is the instinct of the hunted animal to fly, but your invitation to me has been expressed so gracefully that I cannot but accept." Lord Curzon made an interesting speech at the dinner, referring, among other matters, to a Viceroy's horoscope. An outgoing Viceroy, he said, is fêted and dined and toasted before he has gone out to his work, and, indeed, before he has done anything at all. Five years later, upon his return, he slips back into Great Britain almost unperceived, and retires, very likely, into an obscurity which may or may not be merited, but is, at any rate, in striking contrast to the plaudits which attended his departure. Happily, in Lord Curzon's case, such prophecy was unfulfilled.

Lord Curzon's interest in the relics of antiquity were not confined to India. It was through his efforts that Tattershall Castle, Lincolnshire, was saved for the nation when about to be demolished, and through him the castles at Bodiam in Sussex, and Montacute in Somerset, were also preserved.

Lord Curzon was the recipient of many honours bestowed by the learned and scientific world. He was president of the Royal Geographical Society from 1911 until 1914. He was elected Chancellor of the University of Oxford in 1907, when he took a prominent part in the movement for "reform from within." He was Lord Rector of the University of Glasgow in 1908, Romanes Lecturer at Oxford in 1907, and Reed Lecturer at Cambridge in 1913. He was an honorary fellow of Balliol, and held honorary degrees from the Universities of Oxford, Cambridge, Glasgow, and Manchester. He was a fellow of the Royal Society and British Academy, and had accepted the presidency of the English Association not very long before his death.

Lord Curzon in India.

Except in so far as it had a direct influence on economic development or on humanitarian problems, Lord Curzon, during his Indian Viceroyalty, showed no marked interest in scientific research. Science did not appeal to him as a branch of culture comparable to history and literature It is true that, four years before he was appointed Viceroy, he had made a distinct mark as an explorer in the Pamirs, when he solved the problem of the source of the Oxus; but this diversion to physical geography was rather an accidental by-product in a journey mainly devoted to the political aspects of geography and sport. Still, the recognition of this work by the Royal Geographical Society left him with the impression that geography at any rate was a science, and, so far as one could guess from his official and personal activities in India, it gave him the impression also that science was geography Workers in other branches he seemed to regard as having a limited usefulness in solving political and economic problems, and sometimes in assisting his remarkable work in restoring respect for India's unappreciated relics of archæological and historical value. His action in dispersing the fine collection of fishes (which had been prepared by Col. Alcock in the Calcutta Museum), to provide an opportunity for a preliminary display of the historical collections designed for the Victoria Memorial, revealed his want of appreciation of the claims of those forms of culture that had had no part in his earlier education. Fortunately, no other science workers offered obstacles to his activities, and so they could not share to the full the resentment displayed by the zoologists.

Nevertheless, when Lord Curzon realised that science was necessary for economic progress, he recognised the value of laying sound foundations in research which could offer no prospect of definite results in his own time. In this matter he was fortunate in having as members of his Government two Ministers—Sir Denzil Ibbetson and Sir John Hewett—who realised that the development of pure science was essential to solid advancement in its application. Lord Curzon's institution of the Imperial Agricultural Department, by recruiting into one service a strong staff of chemists, botanists, plant pathologists, entomologists, and other specialists devoted to agricultural problems, has already brought to the Indian cultivator direct returns in increased output annually, many times more than the total cost of the new service from its start.

Although most science workers in India during the years 1898 to 1905 remained outside the Viceroy's wide range of active interests, the wiser among them realised that their position was not without some advantages; his zeal for reform was dominated always by a desire for centralised control and symmetry in system of administration—conditions which may have conduced

to increased efficiency, but were never accomplished without trespass on local sentiment or without interference with individual liberty in research work. Fortunately, he found urgent problems in other fields, even more than enough for his apparently unlimited energy and never-failing sense of duty.

In the *Sunday Times* of March 22, Mr. Newman Flower mentions the fact that the night before his operation, which he knew might be fatal, Lord Curzon wrote minute instructions about his forthcoming book on "British Government in India," and this incident reminded me of a somewhat similar illustration of his remarkable regard for small things in spite of greater distractions. In 1905, when the controversy with Lord Kitchener, which led to his resignation, was at its height, Lord Curzon sent me long notes from Simla about certain marble pedestals in Government House which he had asked me, during the previous Calcutta session, to take a personal interest in and to have erected before the arrival of the Prince of Wales.

It was not until after 1916, when war conditions forced upon one many duties of an unfamiliar nature, that one saw further direct evidence to show the great depth as well as width of Lord Curzon's marvellous activities in railway extension, in university education, in public health, in town-planning, in industrial developments, in army administration, and, most remarkable of all, in the complex problems of land revenue which not even an experienced member of the Civil Service professed to understand for any but his own province. His views were expressed in reasoned notes that left one with the impression that each file in turn covered the one subject in which he had specialised. Five years' experience with the Government of India, where the records of his previous work are filed, left me with two outstanding impressions—first, an inexpressible admiration for his energy, thoroughness, and conscientious devotion to India; and secondly, an equally strong feeling of thankfulness that geology was not one of the subjects in which he had occasion to specialise between 1898 and 1905. T. H. HOLLAND.

PROF. A. VON WASSERMANN.

WE regret to record the death on March 16, at sixty years of age, of August von Wassermann in Berlin. He was born in Bamberg, and having studied in Strasbourg, Vienna, and Berlin, early became associated with the Institute for Infectious Diseases under Koch, and it was here that most of his work was done. He ultimately became Director of the Serum department of Koch's Institute, and in 1913 Director of the large Institute of Experimental Therapy of the vast Kaiser-Wilhelm Gesellschaft zur Forderung der Wissenschaft in Dahlem, Berlin. He was also honorary professor in the University of Berlin and was ennobled in 1910.

Von Wassermann's scientific life-work was done in the domain of immunity; he saw its rise and zenith and contributed in no small degree to its development. He was an exceedingly clever man, untiring in his diligence, and in the highest degree efficient if lacking in imagination when compared with the greatest workers in his science. Throughout the development of immunity problems he was constantly on the alert, and felt almost every pulsation of advancement of knowledge with extraordinary acumen. Although rarely the first on the field, he was almost invariably among the first to take full advantage of anything new, and he always added something fresh and clever to work already done. He was a typical "Prussian," somewhat arrogant to his inferiors, but withal a man that was liked. He was a brilliant speaker, and a great star at medical gatherings and congresses, where he was always listened to with attention. As an example of his diligence we may cite the "Handbuch der pathogenen Mikroorganismen" which he edited with W. Kolle. This monumental if somewhat uncritical work appeared in two editions, the first in six volumes between 1903 and 1909, the second in eight volumes with nearly nine thousand pages, all of which was published within two years (1912–1913).

From 1906 Wassermann attained world-wide fame, and his name became almost a household word through his discovery of the so-called Wassermann reaction in the diagnosis of syphilis. In its altered form, this test is practised in every pathological laboratory the world over, and is perhaps the most accurate laboratory test applied to the clinical diagnosis of disease. Wassermann's test was the practical application of a fundamental principle discovered by Bordet and Gengou (1901) of Brussels, and it was characteristic of him that he saw almost immediately how Bordet's work could be utilised for human medicine. Wassermann's name will live long in the annals of bacteriology and immunology. W. B.

DR. WILLIAM F. HILLEBRAND, chief chemist of the United States Bureau of Standards, died on February 7 at the age of seventy-one years, and an appreciative account of his life and work by a colleague at the Bureau of Standards has been published in a recent issue of *Science*. William Francis Hillebrand spent two years at Cornell University before taking up chemistry, most of his training in which was received in Europe. In 1872 he went to Heidelberg to study under Bunsen and Kirchhoff, and from there, he and T. H. Norton published in 1875 their paper on the preparation of metallic cerium, lanthanum, and the mixture then called didymium. Hillebrand's later work showed these metals were trivalent and belonged to the rare earth group. He also discovered the pyrophoric properties of cerium filings. From Heidelberg Dr. Hillebrand went to Strassburg under Fittig, and from there to the Mining Academy at Freiburg. Returning to the United States, he was appointed to the staff of the Geological Survey in 1880, and until 1885 was stationed at Denver. Here was plenty of mineral material to exercise his growing skill as an analyst, and the work was continued after his transfer to Washington. In 1908 he became second chief of the Bureau of Standards. Dr. Hillebrand devised general analytical procedures suitable for different types of mineral and rock, and also special methods for the determination of individual elements, which were placed on record in various issues of the Bulletin of the Geological Survey; silicate rocks were dealt with in 1897, carbonate rocks in 1907, both of which were quickly translated into German. Dr. Hillebrand was a member of the National Academy of Sciences, and in 1906 was president of the American Chemical Society; for many years he served as an associate-editor of this Society's Journal and also of the *Journal of Industrial and Engineering Chemistry*.

Current Topics and Events.

OUR readers will no doubt be interested in the photograph we publish showing Prof. Raymond Dart, of the Witwatersrand University, Johannesburg, with the Taungs skull. Prof. Dart, who is well known to anatomists in Great Britain, was trained under Prof. J. T. Wilson, now professor of anatomy at the University of Cambridge, and worked in London at the Royal College of Surgeons, and under Prof. Elliot Smith at University College in 1919, where he paid special attention to problems of the brain and to the skull of fossil man. Before taking up his appointment in South Africa he was one of three selected by Prof. Elliot Smith from his staff, at

Prof. Raymond Dart with the Taungs skull.

the request of the Trustees of the Rockefeller Foundation, to visit the medical schools of the United States A certain amount of criticism has been levelled at Prof. Dart's nomenclature of the Taungs skull. It is generally felt that the name Australopithecus is an unpleasing hybrid as well as etymologically incorrect. Dr. J. G. de Barros e Cunha, of the Institute of Anthropology, Coimbra, who is among those who take exception to the title on these grounds, also writes to point out that if a new family of *homosimiidæ* is constituted, the generic name should be Homosimis, whereas the generic name, Australopithecus, would require the family name Australopithecidæ. Although it may be a little premature to decide, present information does not force either alternative upon us, as there does not seem to be adequate ground for the creation of a new family. Meanwhile the criticism continues, and in a cable which appeared in the *Times* of March 11, Prof. Dart defends himself with some humour but in a manner which suggests that the niceties of etymology do not greatly appeal to him.

PROF. L. VEGARD sends us the following cable message from Oslo, dated March 20: "Shown by experiments in mixtures of nitrogen and neon at the Leyden Laboratory that auroral line is the limit to which the band N_1 approaches by diminishing size of nitrogen particles." Prof. Vegard described his observations of the luminescence of solid nitrogen, and the structure of the two bands in the green part of the spectrum, called by him N_1 and N_2, in communications to NATURE of September 6 and November 15, 1924.

ALTHOUGH the Coal Conservation Report was issued in 1918, there is still considerable difference of opinion amongst electrical engineers as to the advisability of mapping Britain out into power zones each served by super power stations of high thermal efficiency. It is admitted that there are many small stations which burn fuel extravagantly, but in some of our larger stations the thermal efficiency is about 20 per cent and is still increasing This compares favourably with anything that has been done by the super power stations in the United States, where the power zone system is adopted. There is one aspect of the problem, however, to which more attention should be directed, namely, the possibilities of interlinking various supply systems by reversible motor-generators so that one company can help the other during times of heavy load. Even if the systems of supply be alternating current of different frequency, suitable electrical devices called frequency transformers can be used for this purpose When this is done, in nearly every case the ratio of the average demand on a station to the maximum possible demand is largely increased. The overhead charges are thus considerably reduced and will justify a reduction of price to the consumer. The linking together recently of three power stations in Berlin has had the effect of raising this ratio—the so-called "load factor"—to 57 per cent., and made possible considerable economies. The tables published by the Electricity Commissioners prove conclusively that the larger the power station the higher the thermal efficiency. The main difficulties in the way of getting a cheaper supply of electricity, and a more efficient one from the point of view of fuel consumption, are in connexion with raising the capital required for providing the necessary distribution mains. Various schemes have been suggested for overcoming these difficulties, but no general agreement has yet been attained.

THE pages of American scientific and technical periodicals have for some time provided evidence of considerable activity in the field of colloid chemistry. This is not confined to individual work, but there has been a good deal of concerted action directed towards promoting and facilitating the study of the discipline. The Colloids Committee of the National Research Council some time ago issued a fairly complete bibliography of the subject, and has now put forward a definite scheme for the establishment of a National

Institute for Research in Colloid Chemistry. The scheme itself, some of the general claims of colloid chemistry, and a number of successful applications to technical problems are described in a beautifully printed and illustrated booklet published by the University of Wisconsin. This institution puts forward a number of reasons why the proposed Research Institute should be located in its grounds, one of the reasons being the enthusiastic support given to the lectures and research classes held by Prof. The Svedberg of Upsala during part of the year 1923 and the subsequent "symposium" on the subject. The scheme suggests the raising of a sum of one million dollars, a quarter of which is to be devoted to buildings and equipment and the remaining three-quarters to endowment. A director of research, for whose specified qualifications a salary of 8000 dollars does not seem excessive, a director of the laboratory and two research fellows with salaries of 6000 dollars each, are contemplated. There is very little doubt that the money will be easily obtained, and, whatever view one may take of the possibilities of gregarious research, it is impossible to avoid slightly envious comparisons between the colloids "boom" in the United States and the very inadequate provision for teaching and research on the subject in Great Britain.

THOSE responsible for airship development in the United States and in Great Britain have drawn many comparisons with the development of marine transport. To balance their natural optimism a note of caution may be sounded. The new airships are to displace 140,000 cub. m. volume and 150 tonnes mass of air. A ship of the same volume displacement of water would have a mass displacement of 110,000 tonnes. The air leviathans are, of necessity, bubbles lighter than air. Most marine harbours have protected approaches so that in stormy weather ships pass by degrees from the waves of the open sea to completely protected waters before making actual contact with dock or quay. Where the approaches are bad in certain winds, arriving vessels may have to turn back, an experience not unknown to channel passengers. Unfortunately, all airship harbours are bad in all high winds, and if in spite of weather forecasting an airship is caught outside its shed, it must ride out the storm under power or at the mooring mast. With ships, the maximum hogging and sagging stresses increase until the length of the ship exceeds the maximum wave-length, as is the case with Atlantic liners There is no authoritative information as to the analogous air stresses, but American experience with the *Shenandoah* is held to confirm the belief that these are much greater than the stresses produced by manœuvring in still air. This, then, seems to be the ultimate standard by which the airship will be tested unless it is to remain in its shed until fair weather is predictable with certainty.

THE first manufacture of fused silica ware was a British achievement, and it is satisfactory to learn that the industry which grew from small beginnings at Wallsend-on-Tyne in the early years of this century is still flourishing and well maintaining its pre-eminent position both at home and abroad. Like many other useful inventions, the applications of fused sand and quartz to the construction of laboratory apparatus and to parts of large-scale plant developed at first with extreme slowness, but circumstances arising from the War provided the necessary impetus for their extension: the cutting off of supplies of German porcelain and the recognition of the value of silica condensing-systems for nitric-acid vapour and of silica basins for concentrating sulphuric acid were mainly responsible for the change. Since the end of the War a demand has arisen for silica cooling and absorption plant in the manufacture of hydrochloric acid, both by the old process and by burning hydrogen in an atmosphere of chlorine. Silica stills for the concentration of pure sulphuric acid have also been in request, as silica is the only material that can satisfactorily replace platinum for this purpose. By far the most important new application is the manufacture of gas globes and of bowls for indirect lighting, more fused silica being used for this than for any other purpose. In the immediate future a considerable demand for it is anticipated for making the envelopes of large thermionic valves and the condensers of "radio" sets.

THE number and variety of laboratory appliances made of fused silica are also increasing, and among the latest of these is a mercury condensation pump, which is fully described in the most recent catalogue issued by the Thermal Syndicate, Ltd., of Wallsend-on-Tyne. This pump, measuring 25 cm. in length, is made entirely of fused quartz, and worked in conjunction with a backing pump giving a vacuum of 0·2 mm. of mercury, it provides a vacuum of 0·000002 mm.; it is operated with only 5 c.c. of mercury, can be heated either by gas or electricity, and is water-cooled. The increased use of fused silica ware for scientific and technical purposes would appear to depend mainly upon its price. It is not easy to manufacture; skilled labour is essential, the necessary electrical equipment is costly, and only very pure raw materials, such as sand from Fontainebleau and quartz crystals from Madagascar, can be used. In spite of these circumstances, considerable progress has been made in reducing production costs, and only a big demand is needed to permit of an appreciable reduction in selling price, and to enable silica ware to compete in price with materials which have hitherto been thought to be much easier to produce. The opacity or translucency of articles made from sand is known to be due to the presence of small air-bubbles and not to impurities in the raw materials. These air-bubbles cannot be expelled because the fused sand is very viscous; melted quartz-crystal, on the other hand, is quite mobile. The translucent material is, however, quite suitable for most objects, especially when these are glazed, and for some purposes, for example, the manufacture of gas globes, it is to be preferred.

THE British Non-ferrous Metals Research Association has just issued a report on the research work in

progress or completed under the auspices of the Association. The record is a striking one. A graph which is attached to the pamphlet shows that the expenditure on experimental research, which in 1921, the second year of the existence of the Association, was only 1500*l.*, will amount during the present year to close on 16,000*l.* The most interesting feature of the report is the attention given to the scientific study of alloys. The Council of the Association has taken a very broad view, and most of the work is devoted to fundamental problems rather than to the solution of immediate workshop difficulties It has been decided to establish a small central laboratory, attached to the University of Birmingham, for the use of the Superintendent of Research and also for carrying out preliminary investigations, but the policy of the Association is to have its researches conducted mainly in the universities and other specially equipped laboratories of the country A glance through the pamphlet shows that at least thirty separate research workers are engaged in various laboratories under the supervision of their respective professors or directors. The non-ferrous metal industry is an extensive one, and there are still branches of it which are not represented in the Association; firms which have not yet seen the benefit of co-operative research of this kind cannot do better than study the present pamphlet. One consequence of the present programme, of interest to physicists as well as to metallurgists, will be the exact determination of the physical properties of many non-ferrous metals and alloys, a subject on which information at present is singularly imperfect, as will be realised by any one who consults the standard volumes of tables of physical constants.

"WINDOLITE" is the name given to an aceto-cellulose wire-net reinforced substitute for glass. It offers a very thin film in the meshes of the wire net, and transmits the ultra-violet rays. One sample tested transmitted light right down to 232 $\mu\mu$, while ordinary window glass cuts off rays shorter than about 330 $\mu\mu$. The most active biological rays, so far as the skin is concerned, are about 300-290 $\mu\mu$, and these are the rays which come through with the high sun on clear days. Windolite should be useful for open-air shelters, verandahs, etc. The makers inform us that gardeners find it draws plants less than glass, and that this is not due to great coolness of the garden frame or house. It should be interesting to see how well plants grow under it, and whether the anti-rachitic substance and the growth vitamin A are present more in plants grown with ultra-violet rays than without. The present writer has tried cress, and so far has found no difference on young rats in the growth-promoting power, but that may be due to vitamin A derived from the seeds. Hess in the United States states that market salad has not got anti-rachitic power, but can be given this by radiation. A new glass has also been submitted to us—Lamplough's Vitaglass; this as rolled is a "cathedral glass," but it can be blown clear. It lets ultra-violet rays through down to 275 $\mu\mu$, costs about 3*s.* a square foot, and should be useful for skylights, verandahs, upper parts of windows of hospitals, sanatoria, schools, nurseries, and possibly for greenhouses if fruit and salads are found to be improved in quality by ultra-violet rays. Blown clear it will be useful for bulbs of tungsten filament quartz lamps, allowing us to get some gentle ultra-violet rays from these.

A DESTRUCTIVE tornado struck Annapolis, Missouri, shortly after 1 o'clock in the afternoon of March 18, swept north-eastward across the Mississippi River, traversing Southern Illinois, and at Elizabeth, Indiana, broke into two lesser storms, which tore pathways through Tennessee and Central Kentucky. The *Times* reports that many towns were completely cut off from communication with the outside world, and others were threatened with destruction by fires which broke out among the ruins. Murphysboro, De Soto and West Frankfort in Illinois, Griffin, Owensville and Princeton in Indiana, and Witham in Tennessee are said to have borne the full force of the storm. At South Greenfield, Illinois, a passenger train was overturned by the wind and several persons were killed. In one place about 50 motor-cars were piled in a tangled ruin. Illinois seems to have been the heaviest sufferer, with 645 known dead and 1945 injured. The latest ascertained figure, to March 20, for all five States is 823 dead and 2990 injured, but many bodies are still buried in the wreckage. The storm tore its way over a length of 150 miles. Often its path was only 300 ft. wide. There are places where it uprooted oak trees a foot thick and split apart heavy stone buildings, but left unscathed flimsy cottages and mere shacks.

THE annual report of the Meteorological Office, Air Ministry, for the year ended March 31, 1924, has recently been published. It is the sixty-ninth year of the Office and the fourth year that the cost of the Office has been borne by the Air Ministry. The report shows a large increase in the staff in comparison with a few years ago, as well as an immense increase in the work undertaken. A good deal of reorganisation has been taken in hand The Office has apparently attained its normal condition and little further development is expected for some years Details are given of international work, especially in relation to a common system of reports required for purposes of aviation. The Marine Division has achieved fresh work, including the establishment of the *Marine Observer* and the *Weather Shipping* wireless bulletin Much weather information is gathered for all oceans from voluntary observers. The Forecast Division has made some progress; 84 per cent. of the gale warnings for the whole of Great Britain were followed by gales or strong winds. The ordinary daily forecasts can be obtained, free of charge, by telephone or from broadcasting stations. The Climatological Division deals primarily with the weather of the British Islands, and numerous observations are gathered from all parts of the globe. The Office is interwoven with the Navy, the Army, and the Air Force. Much research is made with regard to the upper air; 8360 single-theodolite pilot-balloon ascents were made during the year, and 236 aeroplane ascents were made by pilots of the

Royal Air Force to determine upper-air temperatures and humidities. The British Rainfall Organisation and observations in connexion with atmospheric pollution afford much valuable material of general utility.

DURING the course of the Pasteur centenary celebrations, held in May 1923, a Pasteur "day" was held throughout France, when badges were sold in aid of the scientific laboratories of the country. Some nine million francs were collected in this way, while the *Matin* raised a further three million francs by subscription A committee under the chairmanship of M. Émile Picard, permanent secretary of the Paris Academy of Science, was appointed to distribute the fund, and a list of the allocations has recently been issued. Grouping the awards according to subject, they are as follows . 2,143,000 francs to physics, of which 1,000,000 francs is reserved for the construction of a powerful electromagnet for the Paris Academy of Sciences, 1,340,000 francs to chemistry; 1,150,000 francs for astronomy, of which 650,000 francs will be for a photographic instrument and for a reflector of 1·20 m aperture, 160,000 francs to mathematics, 120,000 francs of which is for the publication of the works of Henri Poincaré; 190,000 francs to meteorology, 245,000 francs to geography and navigation; 333,000 francs to geology and mineralogy, 630,000 francs to zoology, 640,000 francs to botany; 576,000 to physiology and medicine; 105,000 francs to microbiology, 75,000 francs to agriculture, 600,000 francs for the general biology of the Colonies; 510,000 francs for industrial research and institutions. The three million francs collected by the *Matin* is to be invested and the interest used for prizes and grants. The complete list of the grants appears in the *Revue scientifique* for February 28

THE fourth annual report, just presented, of the National Institute of Industrial Psychology shows a most interesting development of the work in many directions The application of scientific knowledge and methods to industrial problems cannot fail to have far-reaching results not only for the firm or industry studied, but also for the sciences applied for the elucidation of its problems; in the course of the application of the scientific principles new data will be available whereby knowledge will be extended. The investigations for the year cover a very wide field—coal-mining and chocolate-making, dressmaking and restaurant breakages, to mention but a few. The problems studied have involved—protection from extreme heat, effects of long standing, the mental irritation and worry in connexion with breakages, ventilation and atmospheric pollution. Not the least important part of the Institute's work is concerned with the guidance of children just leaving school; this aspect has been considerably enlarged during the year, owing to a generous grant from the Carnegie United Kingdom Trust, and research work is in progress The Institute is also conducting an educational campaign by means of lectures and meetings for both scientific and industrial audiences.

THE Textile Institute, the headquarters of which are at St. Mary's Parsonage, Manchester, with London branch office at 38 Bloomsbury Square, has now received a Royal Charter of Incorporation granted by His Majesty's Privy Council by Letters Patent under the date of March 11. The Charter will enable the Institute, in addition to its other powers, to hold examinations and to grant certificates of competency to practise, teach, or profess textile technology. The Institute was formed in 1910 and registered under the Companies (Consolidation) Act, 1908, as a company limited by guarantee. For several years past the question of qualifications in connexion with membership has been under consideration, but it was not until the existing president, Mr. John Emsley, of Bradford, came forward with a definite proposal, accompanied by a generous offer, that it was decided to petition for a Royal Charter of Incorporation. The object of the Institute in adopting this course was to secure not only a higher general status for the organisation, but also that fellowships or associateships which may be granted shall be issued under satisfactory conditions of authorisation The annual general meeting and spring conference is to take place at Manchester on April 29, whilst the annual conference will be at Edinburgh during Whit-week next. At Edinburgh, the Mather Lecture of the Institute will be given by Prof. A J. Sargent, of the London School of Economics, whose subject will be "The World Problems of Wool and Cotton."

AT the annual general meeting of the Geological Society of London, held on February 20, the following officers were elected. *President*, Dr. J. W. Evans; *Vice-Presidents*, Dr. J. S Flett, Sir Thomas Holland, Prof. A C. Seward, and Sir Arthur Smith Woodward; *Secretaries*, Mr. W. Campbell Smith and Dr. J. A. Douglas; *Foreign Secretary*, Prof. J. E. Marr; and *Treasurer*, Mr. R. S. Herries.

THE Ordnance Survey has published Sheet 44, Mull, of the coloured printed one-inch geological survey of Scotland. The sheet covers an area of involved geological detail and is a beautiful example of fine colour printing. The number of colours used is considerable, and some of them appear in very small area, but the register and general cartographical technique show no flaw throughout the sheet.

WE have received from M. Jacques Boyer, 5 bis, rue Saint-Paul, Paris, a copy of the fourth edition of his "Catalogue de photographies documentaires." It gives a list of the photographic illustrations that he can supply relating to scientific, industrial, and military matters, agriculture, horticulture, geography, aeronautics, automobilism, and portraits of savants and technologists. This last section alone consists of about five thousand portraits, historical characters being taken from the most authentic records. The list of this section is not given. The few sample reproductions included are of excellent quality.

A NEW edition, No. 924, of a catalogue of petrological microscopes issued by Messrs. James Swift and Son, Ltd., 81 Tottenham Court Road, London,

W.1, contains a large and comprehensive collection of microscope outfits for use in petrology, mineralogy, and crystallography The list includes instruments suitable for elementary students, as well as more elaborate types adapted for the most exacting investigations A petrological microscope, being an instrument for observing and measuring the optical properties of rocks, minerals and crystals, requires many special fittings and adjustments which are not necessary in a microscope for use in the biological sciences The models described in the catalogue have been designed primarily for petrological work, and incorporate many of the latest devices for simplifying adjustments and for securing rigidity and accuracy

MESSRS Bernard Quaritch, Ltd , 11 Grafton Street, W 1, have recently circulated Catalogue No 390 dealing with nearly 1900 second-hand works on zoology, botany (including agriculture, forestry, fruit-culture and gardening), and geology As is usual with the catalogues of this bookseller, many choice and rare publications are listed

MESSRS W Heffer and Sons, Ltd., 4 Petty Cury, Cambridge, have just published a lengthy and well-arranged catalogue (No. 248) of second-hand works in the following branches of science —Mathematics and physics, astronomy and meteorology, engineering, wireless telegraphy, agriculture, husbandry, and farriery, anthropology and ethnology, botany, chemistry, chemical technology and metallurgy, geology, mineralogy and palæontology, zoology and biology, physiology, anatomy and medicine Upwards of 3500 books are named, and in addition there is a long list of complete sets of scientific serials which Messrs Heffer have for disposal The list is to be had upon application

Our Astronomical Column.

THE BEGINNING OF THE JULIAN DAY —There is a lamentable state of confusion in the astronomical world as to whether the Julian Day should begin at noon or midnight Some countries, following the lead of the United States, have decided on beginning at midnight But the Astronomical Society of the Netherlands continues the noon reckoning, and many people in the British Isles propose to do the same, some of these quote the fact that no change has been made in the Julian Day table of the Nautical Almanac as registering an official decision in this sense The fact is, however, that no such decision has been reached, and in its absence the wording of the Nautical Almanac remains as before

While it is possible to make a good case for either noon or midnight, the use of different systems in different countries cannot fail to be a source of great confusion, and it is earnestly to be hoped that an official decision will be registered by the Astronomical Union at its meeting in July The present year must in any case be one of confusion, but the sooner that state is ended the better.

THE TOTAL SOLAR ECLIPSE OF JANUARY 24.—The *Scientific American* for March describes this as "the best observed eclipse in history." It was certainly the most populous region that the moon's shadow has traversed since modern methods have been introduced, and the article states that thousands of volunteer observers were engaged in observing the exact limits of the zone of totality and similar researches. Five successful colour photographs of the corona were obtained, and the reproduction of one of them is promised in the next issue "The great spectacle was not marred by so much as a single wisp of cloud."

The times of the beginning and end of totality were telegraphically recorded on two chronographs, one at New Haven, the other in New York, this facilitated the rapid comparison of results, which were thus available in the cable message despatched to Europe the same day. The main feature of the eclipse as a whole was the eager co-operation of thousands of people in a great many directions, including the effect of the shadow on wireless transmission. There is little doubt that the full report will add to our knowledge very considerably.

The errors in the calculated times of beginning of totality, given in NATURE for January 31, were taken from the cabled reports in the *Observer* for January 25. They were very nearly correct, but need a little revision, which can now be made, thanks to a courteous communication from the editor of the *Scientific American* The observed times were late on the predicted ones as follows, Ithaca, 5 sec , Poughkeepsie, 2 7 sec ; New Haven, 4·7 sec , Easthampton, 5·5 sec , mean, 4·5 sec , practically identical with that given before The time at Buffalo was noted as 0 3 sec early, but uncertain owing to cloud

Easthampton, on Long Island, was occupied by a party despatched by the *Scientific American* It was at this station that five successful colour photographs of the corona were obtained by Mr Edward R. Hewitt, who has devised a very rapid process for such photographs

MOVING ABSORBING VAPOURS AT GREAT HEIGHTS ABOVE THE PHOTOSPHERE —Observations with the photographic recording spectrometer as employed by Deslandres in 1910 give the changes in appearance of a line emitted or absorbed by a chromospheric vapour and also its radial velocity Certain filaments are found to develop violent movements, after which they generally disappear or are much weakened. These phenomena are not observed with the spectroheliograph since its narrow second slit is adjusted for a line of the stationary vapour, and when this line is affected by the Doppler effect, it does not pass through it at all M. L d'Azambuja, in the *C R. Acad. Sci. Paris*, January 5, describes six cases which he has observed in the Meudon Observatory from April 1919 to January 1921, using the calcium K_3 line, four of which are similar to that described by Deslandres, and show radial, but no horizontal, movement The two others, however, show rapid and extensive horizontal movements, and in addition important radial ones Maps are given showing the forms and positions of these filaments at different times, together with the positions on the solar disc which they would have occupied had there been no horizontal movement. The filaments were seen at first on the spectroheliograms, but not when the radial velocity became large. The maximum velocity towards the observer of one of the filaments was about 25 km /sec , and it was estimated that it must have reached a height of 225,000 km , or about one-sixth of the solar diameter. No trace of it was left about an hour after it was last seen It is probable that the same phenomena are involved as in the formation of a temporary protuberance at the edge of the solar disc.

Research Items.

INDIAN ARCHÆOLOGY.—A "Note on Prehistoric Antiquities including Antiquities from Mohen-jo-daro" by Mr Ramaprasad Chanda, Superintendent of the Archæological Section of the Indian Museum, Calcutta, which was written for a visit to the Museum made by the Viceroy in December last, gives a valuable bird's-eye view of the archæology of India as illustrated by exhibits in the Museum. The specimens include palæoliths from the Deccan, the Central Indian Plateau, Rajputana, and Eastern India These approach most nearly to the Chellean and Acheulean types Typical neoliths have been collected from nearly all the provinces of India. Of the remains of the Copper Age, which followed the Neolithic in Northern and Central India, the most remarkable are the hoard from Gungeria, Central Provinces, consisting of 424 hammered copper implements and 102 thin silver plates, and a find of nine double axes from the Gulpha River in the Mayurbhanj State Antiquities found at Mohen-jo-daro and Harappe are now on loan in the Museum, among them being the seals with the unknown pictographic script, the pottery, and other objects which, it is suggested, show Sumerian affinities It is not generally known that three seals showing this pictographic script were discovered at Harappa in 1872 and in the 'eighties of the last century and were presented to the British Museum, where they are now exhibited

RACIAL CHARACTER.—An interesting question is raised in two papers published in the Proceedings of the American Philosophical Society, vol. 63, No 2, which discuss the question of potential equality in the various races of man In the first, Dr H N Hall maintains that if the test of history be applied to the negro race, and its past examined with the view of predicting its future, it appears that its mental disposition remains unchanged and seems unchangeable The argument is based upon a study of the culture of the negro and, in this instance, the divine or magical character of the kingship which in Africa, owing to the absence of social or political checks which elsewhere served as a counterbalance to the royal divinity, was incapable of useful development This was the result of a weakness of will in the negro mind which necessitated the support of a superior Dr Goldenweiser, on the other hand, argues that neither physically nor biologically are there any differences in the races of man which permit a grading into a progressive series from the animal upward, as, *e g*, in the case of hairiness, which is extreme in the Australian and European, but slight only in the Negro, Mongol, and American Indian; nor has psychology yet furnished any evidence to assist in grading, while the tests of culture, religion, and morality depend upon a bias determined by our own point of view

POLLINATION AND COMMERCIAL FRUIT GROWING.—Among the many factors that affect the good or bad cropping of fruit orchards, it has become recognised that self-sterility or self-fruitfulness plays a very considerable part Numerous experiments have shown that comparatively few varieties of the more important fruits are able to produce good crops unless they are cross-pollinated from another variety growing near by, and to this fact the poor cropping power of certain orchards is largely to be attributed. C H Hooper, in "Fruit Pollination in Relation to Commercial Fruit Growing" (Fruit Bull. 10, S.E. Agric Coll, Wye), sets out the analysed results of his own and many other records, the compiled lists affording definite guidance to fruit planters The smaller soft fruits all appear to be perfectly self-fruitful, but most need the agency of insects to effect cross-pollination from other plants of the same variety, strawberries being almost the only crop which is chiefly fertilised by wind. In the case of apple, pear, plum, and cherry, however, many varieties are unable to mature fruit with their own pollen, every orchard should thus contain at least two varieties flowering at approximately the same time and capable of cross-fertilisation. The difference between the earliest dates of flowering of varieties of the same fruit is considerable, averaging about twenty days for apples, twelve for pears, nineteen for plums, and three weeks or more for cherries The chief varieties are listed according to whether they are earliest, early, mid-season or late, and an indication is given of the degree to which each is self-sterile or self-fruitful In addition, examples are given of varieties that have been proved by experiment to fruit well together, and the recommendation is made that if trees of one variety only have been planted, about one tree in eight should be regrafted or replaced by another variety flowering about the same time. For apples, Bramley's seedling is suggested as a specially good variety with which to regraft The importance of insects in fruit pollination is emphasised, and bee-keeping is recommended for growers with large areas of a certain fruit Many other factors are recognised as influencing fruitfulness, but the question of imperfect fertilisation of the flower is less usually recognised, and is of sufficient importance to justify special attention being directed to its possible occurrence in cases of persistent poor cropping

THE PRACTICE OF ENSILAGE.—Silage has now become of considerable importance as a stock food, after a somewhat chequered history, and Amos (Journ Min. Agric. 31, Nos 8, 9, 11) outlines the present-day knowledge of the process of ensilage and the methods practised in Great Britain The quality of silage varies much with the conditions of manufacture, sweet, acid and green "fruity" silage all being recognised as desirable types, whereas sour and musty silage cause much loss, as stock often refuse to eat them Almost all herbaceous plants, with the exception of those of the cabbage tribe, can be made into silage, though all are not equally suitable. Tares and vetches, mixed with a supporting crop of oats, rye or beans, give most satisfactory results, providing silage of excellent food value, readily eaten by stock. In other parts of the world maize has proved of the greatest value for silage from every aspect, but as it is very sensitive to frost it is necessary, in Great Britain, to select special varieties bred and selected for habits of quick maturity, Saltger's North Dakota and Longfellow being recommended in place of the White Horse Tooth generally grown Sunflowers, rotation grasses, clovers and meadow grass can all be made into silage when occasion demands, but sunflower silage is less palatable than the others. A silage crop should be cut in a state of maturity rather more advanced than for haymaking, and second crops of seeds may be ensiled just after the corn harvest, maize being left to the last. The best silage results from a crop which is ensiled immediately after cutting, and careful organisation of labour is necessary to attain this end. Care is needed in filling the silo to obtain uniform shrinkage and to avoid undue spoiling and wastage in the upper layers Various methods are advocated to reduce this wastage, but none seem to be of real economic value, and a suitable cover for the top of a tower silo remains to be invented.

BIG BUD OF THE BLACK CURRANT.—We have referred on two occasions (NATURE, May 26, 1923, p. 719, and March 22, 1924, p. 439) to an experiment being conducted at the Crichton Royal Institution, Dumfries, on the eradication of big bud of the black currant, due to a mite. In 1922 the plot of 400 affected bushes was cut down and thoroughly fired The bushes made good growth and flowered in 1923, and again in 1924, but failed to fruit, and have shown marked indications of reversion Finally, last October, 60-80 per cent of the bushes showed re-infection by the mite (Annual Report for 1924, Crichton Royal Institution, Dumfries, p 23) The experiment, therefore, which gave much promise of success during the first year, has proved a failure, and the bushes have now been destroyed

THE CONTROL OF TSETSE FLIES.—In the *Bulletin of Entomological Research*, vol 15, Jan 1925, Dr. W A Lamborn gives an account of an interesting experiment which he has carried out in Nyasaland. In this instance an attempt has been made to ascertain whether it is possible to obtain some measure of control of the species of tsetse fly, *Glossina morsitans*, by artificially increasing the existing numbers of an apparently promising parasite in the fly area The parasite is the small chalcid *Syntomosphyrum glossinæ* Waterst which lays its eggs in the puparia of the Glossina The resulting larvæ devour the tissues of their hosts, thereby destroying them The chalcid is a favourable subject for the experiment, since it is a very prolific and rapid breeder, and is readily dealt with under artificial conditions It has the further advantage of being easily reared from puparia of flesh flies (Sarcophaga) and other Diptera A stock of this parasite was built up in the first instance from eleven females bred out from a single Glossina puparium These parasites were introduced to a number of Sarcophaga puparia, and the resulting chalcids were then utilised to parasitise a still larger number of the host Eventually, a large stock of parasitised puparia were deposited in the breeding places of the tsetse fly, so as to ensure that the emerging chalcids would be liberated in a favourable environment. It was estimated that, on an average, 67 examples of the Syntomosphyrum issue from each puparium, and that more than 277,000 parasites (mainly females) had emerged from the distributed examples Prior to the experiment the normal parasitisation of the Glossina in the area under consideration was found to be only 0·4-0 6 per cent In the year following the distribution, the parasitisation had risen to 8·7 per cent This result, although encouraging, is still a far step from having effected a degree of control of real practical value, nevertheless, it suggests that possibly a still larger output of the parasite might be worthy of trial.

OBSERVATIONS ON BRITISH COCCIDÆ.—Under this title Mr. E. E. Green publishes in the *Entomologist's Monthly Magazine* for February his ninth contribution of the series, on British scale-insects In the present paper four new species are described and figured, and among them *Kuwania pini* n.sp. is notable as providing the first record of a coccid occurring on pines in the British Isles. *Pseudococcus phalaridis* n.sp. from Frimley, Surrey, is recorded as being preyed upon by the larvæ of a fly which was identified by Mr. J. E. Collin as *Ochthiphila polystigma*. This enemy proved so efficient that, a little later on, the particular colony of the new species of coccid had been practically exterminated. Mr. Green suggests that this fly might possibly prove useful to check the ravages of the allied coccid, *Trionymus sacchari*, upon sugar-cane in Egypt and elsewhere. Among other scale-insects the occurrence of *Eriococcus hoheriæ* Mask. on *Hoheria populnea* in the Scilly Isles is of interest since it is the first record of this insect being found away from its original home (New Zealand). It has doubtlessly been imported with the plants from that country The many recent additions made to our knowledge of British scale-insects by Mr Green is but one example of how much work there still remains to be accomplished in working out the more obscure families of the British insect fauna

LIGIA NOVÆ-ZEALANDIÆ IN SOUTH AMERICA.—Prof C Chilton records (*New Zealand Journ Sci and Technol*, vi p 287, 1924) the occurrence at Valparaiso of the shore isopod, *Ligia novæ-zealandiæ*, a species which is found also in New Zealand and Juan Fernandez These isopods carry their eggs in brood pouches under the body until the young are hatched in a form resembling the adult, and hence it is unlikely that they could cross large tracts of ocean The existence of this species in the three places referred to is held to be additional evidence in support of a former land connexion between them The shore amphipod, *Orchestia chilensis*, which lives under similar conditions to the Ligia, is also found on the shores of Chile, Juan Fernandez, and New Zealand

THE DEVELOPMENT OF THE MALE GENITALIA OF HOMOPTERA.—An extensive literature has grown up around the subject of the structure and homologies of the male genitalia of insects The nomenclature of the different parts is highly involved and it is often extremely difficult to trace their homologies in different orders In the *Quarterly Journal of Microscopical Science*, vol 69, part 1, Dec 1924, Dr Hem Singh-Pruthi has an important contribution to this subject with particular reference to the Homoptera In these insects he finds that the male genitalia consist of two pairs of lateral appendages, the sub-genital plates and the parameres, and a median copulatory organ, the ædeagus They are all borne by the ninth abdominal segment They develop from two pairs of appendages only, an outer and an inner, which appear as diverticula of the ventral region of the ninth segment The outer pair develops into the sub-genital plates, and the inner by longitudinal fission becomes two pairs, the inner one of the two pairs so obtained, by the fusion along the median line of its components, forms a single organ, the ædeagus, while the outer is transformed into the parameres Thus the pair of appendages developing into the sub-genital plates does not belong to the eighth segment, as was believed by Kershaw and Muir, but to the ninth, there are no appendages on the eighth in the nymphs or in the adult, nor is there any evidence in favour of these authors' view that the male gonopore in Homoptera, unlike that in most orders of insects, lies between the eighth and ninth sterna, it is in its usual place, behind the ninth sternum The sub-genital plates seem to be the coxites of the ninth sternum; and both the ædeagus and the parameres, derived from a primitively single pair of appendages, correspond to the endopodites

METEOR CRATER, ARIZONA.—A letter to the *Engineering and Mining Journal-Press* for February 7, from Mr L F S Holland, superintendent with the Company the recent drilling operations of which under the rim of Meteor Crater have aroused widespread interest, prompts us to refer once more to the origin of this puzzling "crater" (see NATURE, February 14, p. 244). Mr Holland is chiefly concerned in correcting the many false impressions that have been spread abroad by enthusiastic but largely misleading journalism He confirms the presence of platinum in the

iron meteorites of the neighbourhood, giving the average as one ounce of platinum to five tons of meteorite. An American Sunday paper has published a photograph of an apparently large diamond alleged to have been embedded in an Arizona meteorite Possibly the magnification was not stated, but the truth of the matter is that, while diamonds do occur, they are invariably of microscopic dimensions Of more importance is Mr. Holland's belief that the crater can be best explained by the impact of a shower of meteorites. However, he doubts whether the recent boring went far enough to prove or disprove Barringer's latest theory that the main mass of the meteoric shower became embedded under the southern rim at an angle with the surrounding plain.

THE PETROLOGY OF PENMAENMAWR.—The differentiation of the magma which is now represented by the interesting intrusion of Penmaenmawr is discussed by H. C. Sargent in a recent paper (Proc Liverpool Geol Soc vol xiv, 1924, pp. 82-98) which supplements his earlier work on the various rock-types. Below the 1000-foot contour the rock is a very fresh enstatite-porphyrite with labradorite as the dominant mineral Above this level the plagioclase becomes less calcic, gradually reaching oligoclase, while quartz and orthoclase, mainly present as micropegmatite, steadily increase upwards The author ascribes the differentiation to the inhibition of reaction between the earlier-formed crystals and the residual liquid (shown by the existence of zoned felspars), accompanied by the straining-off of the more siliceous and alkaline material in which the volatile constituents would also be concentrated. He considers it is not safe to assume that sinking of crystals has been an important process, as the grain-size shows no marked variation with height. But the process outlined would not provide an upper concentration of quartz and orthoclase unless the other minerals became concentrated downwards, so that relative movement of crystals and residual liquid is logically implied The influence of volatile fluxes is shown by the increasing turbidity of the felspars as they are traced upwards, by the production of bastite, epidote, and other alteration-products, and by the scarcity of biotite in the higher horizons. It is clearly pointed out that these features cannot be due to weathering In the upper part of the adjoining Craig Lwyd area hornblende is abundant, but so far no explanation is forthcoming to explain this mineralogical difference There seems to be a lateral as well as a vertical differentiation, the south-eastern portion being richer in lime and the north-western richer in potash, thus suggesting that the intrusion may have come from the south-east. Part II. of the paper, not yet published, may throw further light on these speculations.

THE AGES OF RADIOACTIVE MINERALS.—The measurement of geological time by methods based on the decay of radioactive substances is now receiving renewed attention in the United States. The National Research Council has appointed a committee under the chairmanship of Prof. A. C. Lane, to investigate the subject, and the committee has performed a valuable preliminary service by issuing a bibliography of the literature by R. C. Wells. In Canada the Geological Survey has assigned to H. V. Ellsworth the task of applying the methods to Canadian problems. A first paper from his pen is now published in the *American Journal of Science* for February 1925, and gives the results of several new analyses, and a valuable discussion of the principles involved. Hitherto it has been found that when thorium is a noteworthy constituent of a series of minerals, the lead-ratios derived from them are too variable to be trusted, and the tendency has therefore been to ignore such minerals in the expectation that sooner or later the discrepancies associated with thorium would be explained. This course has been followed without detriment to the development of the subject, since for uranium minerals in which thorium was not an important constituent the results have been concordant among themselves and with the geological evidence. Ellsworth, however, in calculating the ages of a series of uraninites from the pegmatites of Ontario, has taken thorium fully into consideration with results that are a little more consistent than they would have been had thorium been ignored The ages vary from 1115 to 1189 million years, with an outside figure based on considerably altered material of 1299 million years These values agree very closely with those obtained from minerals of Middle pre-Cambrian age occurring in Scandinavia, Africa, India, and the United States Before any further advance can be made, apart from the accumulation of analyses, it is essential that the half-periods of thorium and uranium should be re-investigated in relation to the possibility of isotopes of the parent elements, and that the genetic connexion of thorium and uranium, if there be one, or has been one, should be disentangled from the conflicting evidence.

VELOCITY OF DIFFUSION, VISCOSITY, AND EXTERNAL PRESSURE.—Messrs. E. Cohen and H. R. Bruins describe, in the *Zeitschrift für physikalische Chemie*, January 20, a new apparatus for determining the viscosity of mercury at high pressures. The ratio of the viscosity at 1500 atmospheres pressure to that at one atmosphere is found to be 1·048, at temperature 20° C In their previous investigation into the effect of pressure on the velocity of diffusion of cadmium in mercury, at the above temperature, it was found that the ratio of the velocity of diffusion at one atmosphere to that at 1500 atmospheres is 1·051. It follows then that, within the limits of accuracy of the diffusion measurements, the product of the viscosity and velocity of diffusion is the same at one and at 1500 atmospheres. This agrees with the results of previous investigations of the authors, which showed that the velocity of diffusion at atmospheric pressure was inversely proportional to the viscosity, even when the molecules of the diffusing substance and of the medium into which diffusion took place were of equal size.

STARK EFFECT IN METALLIC ARCS.—In the *Japanese Journal of Physics*, vol. 3, p. 45, H. Nagaoka and Y. Sugiura describe an investigation of the Stark effect produced in the electric arc for a number of metals. It was first necessary to stabilise the arc, and this was done by introducing a capacity of more than one microfarad and a large self-inductance between the electrodes, and using a P.D. of 500 volts obtained from a direct current generator. By employing carbon as the cathode and the metal under test as the anode, arcs of 7 cm. in length were maintained with perfect steadiness. The potential changes along the arc were examined, and the electrodes were found to be the seats of strong electric fields due to the presence of an electric double layer which is formed when the current surpasses a critical value. Using a small drop of metal at the anode, fields of the order of 10^6 volts per cm. were obtained, and the Stark effects in these fields were studied. It was found that, with several metals, lines belonging to the same spectrum series were similarly affected, the nature of the change being different for different series, and that the effect increased with the term number.

Mining Research.

THE Executive Board of Mining Research of the University of Birmingham has just issued a report on the work of the Mining Research Laboratory for the years 1921-1924, the report being signed by Dr. J. S. Haldane, who is the chairman of this Board. The report gives an interesting summary of the various researches which are being undertaken, some of which deal with problems of very great importance to the coal industry. Necessarily some of these researches are purely scientific, whilst others are essentially practical, but it is quite obvious that the results of even the first named are likely to find important practical applications. A great deal of work has been done upon the absorption of various gases by coal, and the effect that these phenomena may have upon the spontaneous combustion of coal has been carefully investigated. A certain amount of work has been done on the application of wireless electricity to underground problems, but no definite conclusions appear to have been reached, and the work has, for the present at any rate, been laid aside. A most interesting group of physiological experiments has been carried out by means of an experimental chamber by which it is possible to test the effect of various gases upon men at rest and at work, as the result of these experiments, accurate information as to the effect of carbon monoxide upon those exposed to its influence has been rendered available, and it has been shown that this poisonous gas is absorbed far more readily by men doing work than when they are at rest. Another series of these experiments has tested the suggested new method of treatment for carbon monoxide poisoning as well as for asphyxiation, the value of carbon dioxide for this purpose having been shown by these researches, with which the name of Dr. Haldane is closely associated

Another set of researches, the ultimate results of which may be of very far-reaching importance, are those upon the discoveries of Dr. Bergius dealing with the hydrogenation of coal. It has been found that when coal is mixed with a suitable liquid such as phenol, and heated to approximately 400° C in an atmosphere of hydrogen under a pressure of 155 atmospheres for a considerable length of time, hydrogen is absorbed and a quantity of coal, in some cases up to 40 per cent., is converted into an oil-like liquid. The various constituents of coal have been tested, and it is found that clarain and durain are hydrogenated with comparative facility, but that fusain is very little affected. The possibility of hydrogenating coal under these conditions has thus been definitely confirmed, and substantial yields of liquid products have been obtained, though the nature of these liquids has not yet been fully investigated; it is stated that they appear to contain oxygen, and that it is a question yet to be determined whether it is possible to eliminate this oxygen by further hydrogenation and thus to obtain hydrocarbons. Attention is directed to the fact that the behaviour of clarain and durain is approximately the same, and that the liquids obtained by treating these constituents give almost identical analytical results, and it is suggested that this fact would appear to support Prof. Wheeler's contention that clarain and durain contain constituents of similar chemical type. Although up to the present the results obtained by the hydrogenation of coal have a purely scientific interest, it must be remembered that they only represent the initial stages of a very complex investigation, and that it is quite possible that the ultimate outcome of this may produce results of the utmost economic importance.

Researches on the spontaneous combustion of coal have occupied a considerable portion of the work of the Mining Research Laboratory. It will be remembered by those interested that the Mining Research Laboratory of the University of Birmingham was established to continue the work originally started in the Doncaster Research Laboratory, which was established with the definite object of investigating spontaneous fires in the collieries of that district. It is, however, only proper to point out that whilst the investigation was due in the first instance to the necessity for combating the dangers to which the coal of the district was especially liable, the Doncaster Coal Owners' Committee from the outset placed all its laboratory results freely and fully at the disposal of the entire coal mining industry, and took care to publish all the results obtained by its laboratory staff. This work has been continued at Birmingham, and the oxidisability of different types of coal has been recently studied, as also has the liability of the various constituents of coal to spontaneous combustion. The results have clearly shown that fusain is relatively insensible chemically, and that its oxidation is negligible as a source of heat in initiating spontaneous combustion On the other hand, it is pointed out that bands of fusain, on account of their open physical structure, may play an important part in aiding spontaneous combustion by forming channels through which supplies of air can readily reach the more oxidisable constituents of the coal.

A number of researches, all bearing on the investigation of the oxidation of coal, are being carried on, and it is worth noting that they are being assisted by a grant from the Miners' Welfare Fund, made on the recommendation of the Safety in Mines Research Board of the Mines Department. It is, of course, of the greatest importance to the industry that all the mining research now carried on throughout Great Britain should be co-ordinated by a central authority, not with the view of controlling the work, but mainly to see that no excessive overlapping occurs and to take care that provision may be made for filling up any important gaps in our knowledge which may be left between a number of individual lines of research. It is interesting to note that a number of respirators, most of which have originated in the United States, and are designed to enable men to live for a certain time in an atmosphere of carbonic oxide by oxidising this gas to the relatively innocuous carbonic acid, have been examined, and the results are now being published in the Transactions of the Institution of Mining Engineers.

Finally, we have a group of researches conducted in order to determine the effect of specially hot and deep mines, this work now being carried out in conjunction with a committee of the Institution of Mining Engineers, financed by grants from the Department of Scientific and Industrial Research and the Miners' Welfare Committee on the recommendation of the Safety in Mines Research Board of the Mines Department. Nine reports have already been published as communications to the Institution of Mining Engineers, a form in which they are conveniently available for men engaged in mining operations in all parts of the world The work is being continued, and there is still a large field open for research

It will be obvious from this brief summary of the report that the Mining Research Laboratory of the University of Birmingham is doing work of the utmost value to the mining industry; by far the greater part of this work bears directly upon the safety, health, and welfare of men engaged in the coal mining industry.

Diagnosis of Ankylostomiasis.

THE publication before us[1] aims at giving a connected account of copious and careful work already published in the *Indian Journal of Medical Research*, and since in certain instances it is only the conclusions originally drawn which are now reproduced, their validity cannot be estimated except by reference to the original record

Since all scientific work on ankylostomiasis must rest on accurate diagnosis, great attention is paid to the direct methods by which this is obtainable, namely, to detection of ova and collecting of worms The former was undertaken mainly by microscopic examination of the centrifugal deposit from a strained fæcal suspension, but partly by a special modification of the commonly used concentrative principle inherent in the employment of a heavy salt solution in which hookworm ova float and other fæcal matter sinks.

For the particular floatation technique described, it is claimed that it loses only 7 per cent of ova as against a loss of 50 per cent. or more entailed by other methods, the control employed being apparently the first-mentioned technique Regarding the control, Mhaskar himself finds it inaccurate in that, in the one instance noted, subsequent floating of a counted smear increased the countable ova by 14 per cent The extraordinary inadequacy of these controlling counts is, however, shown by the reviewer's figures, hitherto undisputed, indicating that the average addition required to this particular form of control is not 14 but more than 30 per cent. He finds, too (the report is now in the press), that in his hands Mhaskar's floatation technique indicates an ovum content from one-tenth to one-sixth of that which another, namely, direct centrifugal floatation, shows to be certainly present

It is of interest to refer here to a compilation by Dr. Khalil,[2] who advocates a technique embodying yet another modification of the floatation principle, a saturated solution of common salt being used to float up ova in the inverted cone formed by an Erlenmeyer flask, coarse fæcal matter having first been strained off through a fine sieve. Clearly the intention is that the rising hookworm eggs should become concentrated upon a small area, their removal to a small examination area being thus facilitated. The technique is held to ensure detection of mild infections. It is entirely uncontrolled.

Now the only recorded effort hitherto made (by the present reviewer) to control the effects of floatation in an inverted cone showed that the number of ova recovered from the surface was, on the average, one-tenth of those which a control count indicated as present in the fæces employed, and it has since been shown, as noted above, that that particular control underestimated the ovum content by an average of more than 30 per cent It is not then possible, without evidence offered of the ovum content of the fæces used, to accept as accurate this new gravity floatation method in an inverted cone Presumption of its inaccuracy lies in the many instances here reported where it detected a solitary ovum, whereas, as the available evidence suggests, there were indeed present some twenty or thirty, detectable by adequate means, and in the fact that while 40,000 examinations by the admittedly inadequate smear or centrifugal precipitation methods showed an infection percentage in different parts of lower Egypt of 48 to 97, that obtained in the one village tested by the new technique was only 16·6.

The particular importance of accurate and controlled examinations in Egypt lies in its being apparently the only country in the world where extensive human hookworm infection is limited to *Ancylostoma duodenale* It offers, therefore, unique opportunities for determining whether, as, for example, in ovum output and reaction to treatment, ancylostomiasis and necatoriasis differ—whether there be one ankylostomiasis or two.

Regarding diagnosis by collecting the worms passed after the administration of an anthelmintic, Mhaskar failed to find males in a tenth of cases which were passing fertile eggs, and females in 71·6 per cent. of 500 cases, also passing fertile eggs His conclusion that intensity of infection cannot be gauged by the number of ova found on a slide, though inevitable on his premises, is not necessarily correct.

It is further concluded, without qualification, that betanaphthol thymol and carbon tetrachloride have a fleeting effect on oviposition, their administration rendering diagnosis by search for ova untrustworthy for four days. But the original table, if analysed, shows that in 227 cases treated, 129, or 57 per cent, were not cured, and of the uncured 18, or 14 per cent. only, showed this temporary inability of the diagnostic method employed to detect ova On the other hand, of the 98 cases reasonably presumed cured (for ova were not found in their stools after the third day) 48, or 51 per cent, showed ova during one or more of the first three days. Clearly all factors have not been considered in drawing these conclusions.

The line of treatment used for tea estate labour illustrates vividly the features of the procedure at present fashionable. In one group of estates there was instituted the popular mass treatment without diagnosis. Betanaphthol was administered by scooping it up in a measured spoon It was concluded that as regards 50 grain doses for an adult "it is safe, and even a mistake in excess of the maximum dosage advised is not followed by any serious inconvenience; not much care is required in prescribing this drug, nor is any after-supervision necessary" There is no cross reference under this comment to the following incident On the next set of tea estates, examination of 104 fæcal specimens showed 94 infected Mass treatment was accordingly administered without further diagnostic examinations. Of 1400 persons treated as described with betanaphthol, 2 died and 37 became gravely ill, with the symptoms of poisoning already described in the *Indian Medical Gazette* by Orme and by Corteling, and for Brazil by Smillie. Two men, that is, died of poisoning by a drug administered for an infestation, of their individual possession of which there is no evidence. The betanaphthol was proved to be chemically pure.

In the matter of prevention, which is of course summed up in the word soil-infection, it is shown that larvæ identified as those of hookworms persisted in trenched nightsoil for 13 to 14 weeks, and in the surrounding soil for 6 to 9 weeks; but it is concluded that larvæ do not migrate from the place of development. Larvæ found in the soil after 16 weeks were held in all cases to be non-parasitic, for it is stated that, apparently in some 14 experiments, counted numbers of these larvæ were placed in a drop of water left lying on the skin of the forearm for half an hour, and that every one of these larvæ was afterwards pipetted off and accounted for.

The valuable work here detailed merits close examination, however much one may feel compelled to dissent from the main conclusions.

CLAYTON LANE.

[1] Report of the Ankylostomiasis Inquiry in Madras. By K. H. Mhaskar. Indian Medical Research Memoirs, Volume No 1 October 1924.

University and Educational Intelligence.

CAMBRIDGE.—The report of the Appointments Board for the year 1924 presents interesting reading The number of appointments found for graduates of the University has increased to 400. The chief groups are educational appointments, 123; manufacturing and technical appointments, 103, administrative appointments in commerce and industry, 90; agriculture and forestry, 25, and colonial administration, 16. The board notes a dearth of candidates for the great public services overseas.

The annual report of the General Board of Studies on the progress and condition of certain University departments for the year 1923-24 refers to a number of facts already noted in these columns. A general slight decrease in the number of students in the scientific departments is noted. Sir Frederick Gowland Hopkins points out that the amount available for research from the Dunn Bequest, 2400*l* per annum, did not suffice to meet the needs of his 40 research workers and that the maintenance of research on this scale had involved his department in financial difficulties. Prof. Seward reports his inability to find money for the stipend of the curator of the Botanical Museum. Prof. Inglis reports that arrangements have been completed for the course for officers of the Royal Engineers to be extended to two years so that these officers would take the Mechanical Sciences Tripos Prof Dean emphasises the value in the teaching of pathology of its recognition as a subject in Part II of the Natural Sciences Tripos. It has brought the subject from the pass standard of the medical curriculum to the honours standard of the Tripos. Increased accommodation has led to much improvement in the arrangements of the Museum of Zoology, especially in the case of the entomological collections.

Sir Humphry Davy Rolleston, Bt., president of the Royal College of Physicians, has been appointed Regius professor of physic in succession to the Right Hon. Sir Thomas Clifford Allbutt

EDINBURGH.—At the meeting of the University Court on March 16, intimation was made that His Majesty, on the advice of the Secretary for Scotland, had appointed Dr. John Fraser to be Regius professor of clinical surgery in succession to Sir Harold Stiles, who resigned on March 20.

Leave of absence for May and June was granted to the professor of materia medica to enable him to deliver the Dohme Memorial Lectures at Johns Hopkins University, Baltimore. Prof. Cushny proposes to deal in these lectures with the subject of optical isomers in biology.

The Munro Lectures on anthropology and prehistoric archæology will be delivered by Sir Arthur Keith in May next.

Mr. K. G. Fenelon, lecturer in economics, was appointed in connexion with the educational courses for railway staffs to deliver the course of lectures for 1925–26, the subject being railway economics.

A letter was received from the Forestry Commission stating that the Commissioners had had under consideration the question of mycology in relation to forestry work, that they regarded it as a matter of urgency that a means should be found to combat fungoid diseases, which were causing the department serious loss in its nurseries and young plantations, and that they were prepared to make to the University in respect of the year commencing April 1 next a grant not exceeding 500*l*. for research in this connexion to be carried out by the Botanical Department of the University. The Court welcomed the proposal and concurred in the arrangements suggested.

LONDON.—Keddey Fletcher-Warr Studentships, each of the value of 200*l*. a year for three years, have been awarded to Mr D C Harrison (King's College), for research in biochemistry, and to Dr N A. V. Piercy (East London College), for research in aeronautics.

ST ANDREWS.—At a meeting of the University Court on Friday, March 20, Mr. William W McClelland, principal lecturer in education in Edinburgh Training Centre and lecturer in the University of Edinburgh, was appointed to the Bell chair of education, the duties of the chair embracing the University lectures in education at St. Andrews and Dundee Prof. McClelland will also act as Director of the St Andrews Provincial Committee for the Training of Teachers

Prof. A E. Taylor, formerly professor of moral philosophy at St Andrews, now occupying the chair of moral philosophy at Edinburgh, has been appointed to deliver the Gifford Lectures in the session 1926–1927

THE governing body of the Northampton Polytechnic Institute, St. John Street, Clerkenwell, E C 1, is inviting applications for the headship of the electrical engineering department. Particulars of the appointment and forms of application are obtainable from the principal Completed forms must be returned by April 18 at latest

A SENIOR lecturer in dental anatomy, physiology, and histology will shortly be appointed by the University of the Witwatersrand, Johannesburg Particulars and forms of application may be had from the Secretary, Office of the High Commissioner for the Union of South Africa, Trafalgar Square, W C 2. Completed forms and testimonials (in each case three in number) must be sent in by April 11 at latest

A REPORT on facilities for advanced study and research in the universities and university colleges of England and Wales is published in the March number of the *University Bulletin*, the organ of the Association of University Teachers The report is the work of a committee comprising the Principal of the University of St. Andrews and nine professors of the Universities of Oxford, Cambridge, London, Leeds, Liverpool, Sheffield, and Bristol, the Imperial College of Science and the University College of Wales The committee adduces the usual reasons for the improvement of salaries, the lightening of the teachers' load of routine work, and the granting of special leave of absence for the purpose of pursuing an investigation or completing a piece of original work, and states that no teacher should be expected to give more than half his working day to routine University duties It is suggested that in each territorial region a joint body representing the University and the secondary schools of that region might with advantage be set up for the purposes of such co-ordination of curricula and adjustment of university entrance requirements as would tend to free the universities for their proper work The institution of research professorships is regarded with disfavour by all the local branches of the association, and the committee agrees that it is not to be recommended as a general policy though useful in special circumstances Special attention is directed to the policy adopted by the University of Birmingham of maintaining a research fund administered by a joint standing committee. The same number of the *Bulletin* contains articles on library co-operation, examinations, the University of London, and income tax on salary earned abroad—showing that this journal no longer confines itself mainly to recording the activities of the Association of University Teachers.

Early Science at Oxford.

March 30, 1686. Dr. Plot communicated coal from Amrath in Pembrokeshire, which being spit on gave an Ink for writing, as was found true by experiment before ye Society

March 31, 1685. Mr. President was pleased to give the Society a more full account of his extracting the Root of a Number of 53 places in the darke, by the help of Memory

Upon occasion of a Discourse at a meeting of the Philosophicall Society at Oxford (March 24, 1684–5) concerning the advantage, which those may have (as to Memory, & the application thereof) who want their sight, Dr Wallis confirmed it by this consideration, that even we, that have our eye-sight, can yet with more advantage apply our Memory (in matters of intent consideration) by night, in the dark, when all things are quiet, than by day, when sights and noises are apt to divert our thoughts: And gave instance in his application of his own memory, by night, (in performing Arithmeticall operations in great numbers) better, than by day he could have done: and, even by day, we may better do it with our eyes shut, than open

Having had the curiosity heretofore to try, how far ye strength of Memory would suffice me to performe some Arithmeticall Operations (as Multiplication, Division, Extraction of Roots &c) without the assistance of Pen, & Ink, or ought equivalent thereunto, And finding it to succeed well for instance in extracting the Square Root from numbers of 8, 10, 12, or more places: I proceeded to try it (with successe) in numbers of 20, 30, or 40 places On December ye 22d, 1669, I had (by night, in the darke) extracted the Square Root of 3 (with cyphers adjoyn'd) continued to ye twentieth place of Decimall Fractions. I did that same night (by darke, in bed, without any other assistance, than my memory) propose to my self (at all adventures) this Number of 53 places

2,4681, 3579, 1012, 1411, 1315, 1618, 2017, 1921, 2224, 2628, 3023, 2527, 2931,

and found its Square Root of 27 places to be

157, 1030, 1687, 1482, 8058, 1715, 2171 ferè

These numbers (having fixed them in my Memory, by repeating the same operation a night or two after) when a friend made me another visit, March 11th following, I did dictate to him from my memory (having not before committed them to writing) for him to write down and examine And did afterwards write them down myself

April 3, 1688. Mr Walker shewed the Society some drop Microscopes, and the manner of makeing them

Mr. Charlet acquainted the Society of a Cock with three legs, and two anus's at William Greenhill's Esqr at Abbots Langley near St Albans.

Several formed Stones were shewed the Society viz *Cornua Ammonis, Mytiloides, Solenites, Conchites;* several Stones called St. Cuthbert-beads, and other stones exactly of the figure of a Cocks Spur, which, as Dr Plot related, are only the pointes of those Stones called St Cuthbert-beads, most of which were found in the Quarries on the side of Wotton-under-hedg-Hill in Glocestershire, as also a great hollow mass of Iron Oar, brought from St Vincents Rocks near Bristol, which in the concave was beset with hexangular crystalls; as also some masses of Lead Oar Oar found on Lye-Down near Bristoll, from which it is said they extract Silver in a Cup alle standing under the aforesaid Down

Upon the sight of which the President acquainted the Society that at Stanton-Prior *Cornua Ammonis* were the natural stones of ye place

Societies and Academies.

LONDON.

Royal Society, March 19.—Sir William **Hardy** and Ida **Bircumshaw**: Boundary lubrication: plane surfaces and the limitations of Amontons' law (Bakerian Lecture). When the slider has a plane face the coefficient of friction is a function of the load, decreasing as the load increases, until a point is reached beyond which the coefficient is independent of the load When it has a spherical face, the coefficient is always independent of the load The coefficient is a measure of the efficiency of the lubricating layer with respect to one variable—the load Recollecting that the pressure between the bearing surfaces must be very great when the slider has a spherical face, the above results show that with low pressure the efficiency of the lubricant increases as the pressure increases until a limit is reached, beyond which Amontons' law holds It is probable that, during the first period, when Amontons' law does not hold, the slider is floating on a layer of lubricant the thickness of which is a function of the pressure, whilst in the second period, where Amontons' law holds, all lubricant which can be squeezed out has been squeezed out, and a layer of constant molecular composition has been reached In the first period friction is adjusted to the load by variations in the thickness of the layer of lubricant, and in the second period by the elastic forces between the atoms.

Linnean Society, February 5.—G P. **Bidder**: Growth and death A water-borne organism may grow indefinitely, but swiftly moving land-animals must maintain a relation between their weight and the cross-sectional area of their bones and muscles Men and plaice before puberty alike show additions to their weight in approximately geometrical progression for equal intervals of time, alike after sexual maturity they show an approximately arithmetical progression In the plaice the annual increment remains to a great age positive. In man the arithmetical progression shows a difference with negative sign, and from 28 (the age of greatest reproductive fertility) onwards there appears to be a constant net loss of protein material, amounting annually to $(0{\cdot}8 \pm 0{\cdot}15)$ per cent. of its weight at 28. The mechanism of the adult body is set after sexual maturity to a certain annual balance of profit and loss for water-borne animals this may be a positive increment and life may be eternal; for terrestrial animals the length of life depends on the nearness to equality of profit and loss. A positive annual increment, however small, will eventually bring about death from gigantism; it is not improbable that this has been, and possibly is now, the form of death in some quadrupeds. A negative annual increment, however small, determines a date at which all capital resources will disappear. We die, therefore, as an alternative to becoming giants.

Faraday Society, February 16.—A J. **Allmand** and V. S. **Puri**: The effect of superposed alternating current on the anodic solution of gold in hydrochloric acid. The only well-known case in which a superposed alternating current is used in technical electrolysis is furnished by the Wohlwill modified gold refining process. Pure gold anodes in hydrochloric acid solution were employed, using direct current alone, and also the same with alternating current superposed. Anode potentials have been measured throughout.—C. H. **Desch** and Eileen M. **Vellan**: The electrolytic deposition of cadmium and other metals on aluminium. Where lightness is of importance, as

in aeronautical work, the deposit should be thin, and the choice of metals is further limited by the tendency of many deposits to detach themselves. Preliminary experiments having shown that cadmium was better in these respects than copper or nickel, an investigation into the best conditions of deposition was undertaken. Other methods of protection are on the whole more useful, but comparison with other metallic coatings shows a great superiority in favour of cadmium, even under the severe test of exposure to a salt spray. The deposit has a pleasing appearance and a good colour.—W. M. **Thornton** and J. A **Harle**: The electrolytic corrosion of ferrous metals The most direct way of subjecting a metal to the influence of active moist gas is by electrolysis Since rust is almost entirely oxide, it is only necessary to make the specimen the anode of a cell containing slightly acidulated water in order to obtain conditions of exposure to moist oxygen which are perfectly under control. Not only have pure metals definite rates of corrosion according to Faraday's laws, but also every ferrous alloy examined has a specific rate of electrolytic corrosion by which it can be identified with certainty. This may prove a basis for a systematic comparison of the behaviour of ferrous alloys under all conditions of exposure which result in oxidation.—S. **Glasstone** Overvoltage and surface forces at the lead cathode. The addition of ethyl or methyl alcohol, or acetic acid, to aqueous solutions with various hydrogen ion concentrations lowers the surface tension and also the overvoltage Substances like iso-amyl alcohol, which are sparingly soluble in water and lower its surface tension considerably, cause the overvoltage of a lead cathode first to increase and then to decrease as increasing amounts are added. A complete theory of overvoltage must take into account the surface forces involved in bubble formation.—M **Shikata**. The electrolysis of nitrobenzene with the mercury-dropping cathode Part I The reduction potential of nitrobenzene Nernst's formula, modified by the adsorption isotherm, was verified in acid and alkaline solutions An abnormal reduction potential in alkaline solution was found and "neutral salt actions" were observed The reduction due to the simple deposition of hydrions, and to the ionic splitting of water in neutral solutions, was distinguished by the current-voltage curves Part II The influence of the cathodic potential on the adsorption of nitrobenzene A maximum reduction current followed by a minimum, due to certain potentials, were observed in the reduction of nitrobenzene. The formation of a maximum reduction current was explained by the de-sorption due to the applied polarisation potential of the mercury drops Observed influences of neutral salts upon the R.P. and on adsorption were explained by the "salting-out" action. The method is applicable to quantitative and qualitative micro-analysis.—J R. H. **Coutts**: The law of distribution of particles in colloidal suspensions. a note on the specific volume of a gamboge suspension. Measurements of the specific volume of a dilute gamboge suspension, to an accuracy of about 1 in 60,000, verified the assumption made by Porter and Hedges, namely, that no significant contraction or expansion takes place in the formation of such a suspension.—W. W. **Barkas**: On the distribution of particles in colloidal suspensions. The results of measurements made in centrifuged solutions of gamboge, silver and copper, of the sizes of particles given by the formula of Porter and Hedges as compared with the sizes given by the law of centrifuging developed by E. Talbot Paris, are discussed. The same values of the radius are given for copper by the two methods; for silver the radius from the distribution is higher, and for gamboge lower than from the centrifuge. The radius given from the distribution of uncentrifuged solutions is in similar agreement with that given from the rate of fall of the cloud particles by Stokes's Law. If the solution under examination could be effectively shielded from changes in temperature, the determination of the distribution would give an accurate measure of the mean size of the particles in a solution, provided their density was known Over a considerable range of concentrations, the level at which the distribution is sensibly uniform is quickly reached and the limiting concentration is directly proportional to the number of particles present in the solution

Royal Statistical Society, February 17.—E S **Russell** and T **Edser**: The fishery statistics of England and Wales. The number of fishermen engaged in the sea industry is about 40,000, and all the waters of the continental slope, from the Barents Sea down to the Atlantic coast of Morocco, are visited by English trawlers in their search for fish, and to the north-westward the waters round Iceland and Faroe are regularly frequented. The value in 1923 of the catch of bottom-living or demersal fish, the great bulk of which is brought in by steam trawlers, was 12,500,000*l*. To this must be added the value of a catch of pelagic or surface-living fish caught mainly by drift nets, which amounted in 1923 to 1,500,000*l*. The principal pelagic fish is the herring, of which more than 3,000,000 cwt was landed in 1923 Statistics of real value date back to 1886, and marked improvements were made in 1903 and 1906 It is now possible to allot catches to rectangular areas of 1° of longitude by 1° of latitude, and the catch per 100 hours' fishing can be worked out for steam trawlers and certain other classes of vessels An international system of groups of these rectangular areas has been evolved and is accepted by the nations adhering to the International Council for the Exploration of the Sea

Royal Meteorological Society, February 18.—Miss L D **Sawyer** The effect of pressure distribution upon London's sunshine in winter The results were based on an analysis of the pressure types during the five winters ending 1921-22, and the amount of sunshine recorded in different parts of London each day Near the centre of a depression the average sunshine is less than 0·5 h per day, and near the centre of an anticyclone the figures are equally poor except with E S E. breezes If the pressure centre is at least two or three hundred miles away, the average with anticyclonic conditions is about two and a half times as great as with cyclonic, while a "neutral distribution" (neither cyclonic nor anticyclonic) is almost as sunny Records show that Hampstead and Greenwich are both almost as sunny as South Farnborough when the air reaches them before passing over London, but Hampstead loses more than an hour a day with S E winds and Greenwich as much or more with N.W. winds.—S. **Chapman**: On the changes of temperature in the lower atmosphere, by eddy conduction and otherwise. For a number of years hourly observations of the temperature of the air have been made on the Eiffel Tower, at the base, the top, and two intermediate heights, *i.e* of the change of temperature in the lowest stratum of the atmosphere, 300 metres, or nearly 1000 ft thick Eddy conduction is not the predominant cause of the temperature changes, and the effect of the remaining (major) cause, probably radiation, is far from being constant with respect to height. The temperature changes wrought by conduction are greatest at midday and small at night; those produced by radiation are greatest soon after dawn (when the air is being heated rapidly) and

in the late afternoon (when the air is cooling).—N. K. **Johnson** and O. F. T. **Roberts**: The measurement of the lapse rate by an optical method. Theoretical expressions have been deduced by various authors connecting the apparent vertical displacement of a horizontal ray with the length of the ray path and the vertical gradient of temperature in the atmosphere. The results of the observations confirm the theory within the limits of accuracy of the measurements. With certain limitations, the optical method affords a practical means of determining the vertical gradient of temperature.

Geological Society, February 20.—J. W **Evans** Regions of tension, evidenced by joints, slip-faults, and dykes (Anniversary Address) The different causes of local tension were given, including torsion; but although the latter was found by Daubrée to give systems of fractures at right angles to one another, these might also be produced in any area with maximum and minimum directions of tension Western Europe is largely characterised by tension towards the south-west, but north-westward tension prevailed in north-western Ireland and north-western Scotland The south-westward tension appears to represent a slow drift towards the Atlantic "deep" in the Bay of Biscay running north-westwards from Cap Breton, and the north-westward tension seems to represent a drift towards the "deep" trending north-eastwards between Rockall and Ireland These "deeps" themselves are to be attributed, not to "foundering," but to a drift of the "sial" masses of the Central Atlantic banks to the south-west and north-west respectively

EDINBURGH.

Royal Society, February 9.—W. L. **Calderwood**: The relation of sea growth to the spawning frequency in *Salmo salar* From the systematic study of scales of salmon and the calculation of age lengths, the growth of fish which return from the sea to spawn in early life is contrasted with the growth of those which remain for several successive years to feed and grow to a large size without spawning The first and frequently the second year's growth in the sea determines which habit is followed.—F J **Cole**: A monograph of the general morphology of the myxinoid fishes based on a study of Myxine Part VI. Blood vascular and lymphatic systems of Myxine. The anatomical relations of the two systems and the circulation of the blood from one to the other is described An extensive true lymphatic system is present as apart from the so-called veno-lymphatics which belong strictly to the venous system. A fourth (cardinal) heart is described. The liver is an hepato-pancreas, the pancreatic tubules being associated with the branches of the portal vein in the liver parenchyma.—Sir Thomas **Muir**. Theory of compound determinants from 1900 to 1920

MANCHESTER.

Literary and Philosophical Society, February 3.—W. L **Bragg**. (1) Model illustrating the formation of crystals When a solution of a salt is evaporated, positively and negatively charged ions, which are at first distributed in the solutions, pack themselves into a regular pattern. A series of electro-magnets hung by long wires represent these ions They can be charged with opposite polarities by passing an electric current through them. At first they swing about freely in all directions, then as the attractive force increases they group themselves into pairs (molecules), and these pairs pack together to form a regular crystalline body in two dimensions. A slight variation of the experiment shows the difference between acids and bases and the formation of complex acid groups according to the theory of Kossel. (2) Exhibit of diffraction gratings constructed to illustrate the effect of crystals on X-rays. By ruling gratings in which the lines are complex, many of the diffraction effects observed in crystals may be simulated. The gratings are made by taking a contact print from a glass plate ruled with a number of fine lines such as is made for the half-tone printing process. Instead of taking one print, two or more are taken, the plate being moved a very small distance between each exposure, and the times of exposure varied. Thus each line in the grating has several components of different intensities just as each molecule in the crystal is composed of several atoms, all the components or atoms scattering the light or X-rays respectively Very striking diffraction effects exactly like those got in X-ray analysis are obtained.—R W. **James** and W A. **Wood**. The structure of barium sulphate Examination of the spacings of the different planes shows that the space-group is V_h^{16} and that the unit cell contains four molecules and has the dimensions $a = 8{\cdot}852$ Å, $b = 5{\cdot}430$ Å, $c = 7{\cdot}132$ Å By examining the intensities of the different spectra it has been possible to place the atoms with some accuracy The intensities of the spectra of lower order are consistent with the assumption that the SO_4 group is a tetrahedral arrangement of oxygen atoms around a central sulphur atom, the distance sulphur to oxygen being about 1·5 Å The barium and sulphur atoms lie on the reflexion symmetry planes of the structure which are parallel to (010), and necessarily two of the oxygen atoms lie on these planes also.—E C S **Dickson** Experimental demonstration of the Magnus effect: principle of the Flettner rotor ship

PARIS.

Academy of Sciences. February 9.—Charles **Richet**, M **Oxner**, and J. **Richard**. Cooked food and raw food in feeding fish. An account of experiments carried out at the Oceanographic Institute of Monaco on *Cantharus griseus* The fish fed on raw meat showed no differences from those fed on cooked meat up to the 50th day, but after that period the former steadily gained in weight on the latter.—H **Vincent** The pathogeny and conditions of maintenance of the coli bacillus The blood of animals immunised against the *B. coli communis* is rich in the antibody, but the urine contains little or none The immunity does not extend to the kidney or bladder.—G. **Friedel**: Remarks on a recent communication relating to the fatty acids With reference to a recent note of M. Trillat, the author emphasises that the smectic state as defined by him is very different from the crystalline state, and the term cannot be applied to crystals.—Georges **Giraud**: The generalised problem of Dirichlet, Non-linear equations of m variables.—F. **Defourneaux**: Some applications of electrospherical polynomials to the theory of numbers.—Maurice **Fréchet**: Abstract spaces.—Vladimir de **Belaevsky**: The rupture of the Bouzey dam. The deformations of a reduced model ($\frac{1}{10}$) of the Bouzey dam constructed in xylonite have been studied by an optical interference method. From the results of the measurement the conclusion is drawn that the bursting of the Bouzey dam in 1895 was produced by rending.—Henri **Malet**: The idea of the variation of mass, deduced from the formula of the addition of the velocities taken by itself.—Maurice **Le Besnerais** and Raoul **Ferrier**: The electrical constitution of the ether.—Marcus **Brutzkus**: The realisation of chemical reactions in compressors.—

F. **Croze**: The structure of the line spectrum of ionised oxygen.—B. **Szilard**: A new method of examining the interior of pearls. The pearls, immersed in thick cedar oil, are viewed directly by the microscope. Pearls formed on a nucleus of mother of pearl can be readily distinguished by this method from natural pearls.—**Nobuo Yamada**: Particles from polonium with a long path.—Fred **Vlés** and Edmund **Vellinger**: The physico-chemical properties of gelatin; the rotatory power The results of measurements of diffusion, multi-rotation and rotatory powers of solutions of gelatin are given, the variable being the hydrogen ion concentration.——**Lespieau**: The glycol CH C.CH(OH)·CH_2(OH). This glycol was obtained from the chlorhydrin CH : C . $CH(OH)_2$. CHCl as starting point, through the ethylene oxide CH : C . CH_2—CH_2. Its formula was established by its combination with phenyl isocyanate and by titration with bromine It is remarkable as being the first true acetylene derivative failing to give a precipitate with ammoniacal cuprous chloride.—Marcel **Godchot**: Octohydro-phenazine.—Charles **Chéneveau**. The formation of natural dull amber. A transparent pine resin can be rendered opaque by treatment with water at 50° C, under similar conditions peach and cherry gums do not turn opaque, but swell up and form a gel. During the tertiary period the influence of the temperature of the Baltic regions, then tropical, together with the effect of time, would be sufficient in the presence of water at atmospheric pressure to convert the transparent resin into opaque resin.—L. **Royer** New observations on the orientation of ammonium iodide by muscovite mica.—Ch. **Lormand** Analysis of the thermal waters of Chaudesaigues (Cantal).—C. **Dauzère**: The atmospheric vase and the sea of clouds. Observations made at the Pic du Midi.—R **Kuhner**. The nature of the cystids in the Basidiomycetes.—A. **Hée** and R. **Bonnet**: The influence of the dissolved oxygen content of the water on the respiration of submerged plants For the four species of plants studied (*Myriophyllum epicatum*, *Elodea densa*, *Cabomba caroliniana*, *Elodea canadensis*) the intensity of the respiration was not sensibly modified by variations in the dissolved oxygen in the water between 3 cc. and 24 cc of oxygen per litre.—E **Michel-Durand**: Under what form do the tannins exist in Spirogyra? The tannins of these plants are almost completely extracted by acetone and amount to about 3 per cent. of the dry weight. The insoluble tannin compounds, normal in higher plants, are absent from Spirogyra.—Henri **Piéron**: The differential characteristics of the working of the retinal cones and rods.—Jules **Amar**: The stages of vital coagulation.—Jean **Roche**: The respiration of the tissues in avitaminosis and inanition A recent theory, put forward independently by Hess and Abderhalden, attributes to the vitamins a rôle of primary importance in the mechanism of cellular oxidations. According to this theory, avitaminosis is an impoverishment of the cells in respiratory ferments. Experiments on tissue respiration described have given results in opposition to this theory.—P. **Fredet** and René **Fabre**: Study of the localisation in the organism of the alkyl derivatives of malonyl urea. In injections of diethylmalonyl urea (veronal) and allylisopropylmalonyl urea, it has been proved that these compounds fix themselves selectively on the nervous centres, brain and spinal column.—Mme. **Phisalix**: Autopsy of a reticulated python (*Python reticulatus*) measuring 5·75 metres in length.—Robert **Weill**: The nematocysts and spirocysts of the Cœlenterata. Mode of working and differential characters.—O. **Duboscq** and P. **Grassé**: The parabasal apparatus of the Flagellæ and its signification.

WASHINGTON, D.C.

National Academy of Sciences (Proc. Vol. 10, No. 12, December).—H. B. **Wahlin**: The mobilities of the positive ions in helium. The mobility of the positive ion in air decreases if the ion is allowed to "age" before it enters the field in which its mobility is to be measured, due probably to the fact that ions consist of clusters of molecules and not of single charged molecules. A similar result was obtained in helium, but the mobility curves show two definite breaks, due possibly to the presence of two types of aged and two types of unaged ions.—G. P. **Baxter** and H. W. **Starkweather**: The density of oxygen. Little novelty of method is claimed. Three globes were used and weighed by direct comparison with similar exhausted sealed globes. Oxygen was prepared by (1) electrolysis of dilute sulphuric acid; (2) electrolysis of aqueous sodium hydroxide, (3) heating potassium permanganate, (4) heating potassium chlorate and manganese dioxide The average value for the density found from the three series of experiments considered most trustworthy is 1·42901 corrected to 0° C and 760 mm at sea-level, lat. 45°, and this is also the average for the whole set of 22 experiments, each of which consisted of three determinations The value generally accepted hitherto is 1·42905 The new density gives the limiting value of the molal volume under standard conditions as 22·415 litres.—C. T. **Brues**: Observations on the fauna of thermal waters The observations refer chiefly to the thermal springs of the Yellowstone National Park Characteristic of the conditions are the high temperature, presence of unusual quantities of inorganic salts, deficiency of dissolved oxygen, and excess of carbon dioxide. Plants without chlorophyll exist in water at 70°-89° C, and green algæ at 60°-77° C, animal life is found in water at 46°-52° C, but is scarce above 40°-42° C The present fauna includes Protozoa, Arthropoda, Mollusca, and cold-blooded vertebrates, and is generally similar to a brackish-water fauna. This seems to be due to their both deriving from fresh-water organisms.—W. E. **Castle**: On the occurrence in rabbits of linkage in inheritance between albinism and brown pigmentation A race of rabbits with brown pigmentation of the coat gave 25 per cent. pink-eyed and white-coated young with brown at the extremities (Himalayan albinism). Brown is recessive to black pigment and Himalayan albinism to brown The two recessive characters are relatively loosely linked in inheritance. Previous cases of linkage in mammals show less than 20 per cent. of crossing over, here more than 40 per cent. occurs.—E. **Hille**: A general type of singular point.—J. W. **Alexander**. Topological invariants of manifolds.—F. G. **Benedict** and Cornelia Golay **Benedict**: (1) The neutral bath and its relation to body heat Oxygen consumption was used as an index of the basal metabolism of four trained subjects, one woman and three men, first in the laboratory at 15° C and afterwards in a bath of water at 33°-38° C. (neutral bath used as a sedative in psychiatric clinics) The oxygen consumption of the men showed an increase, while that of the woman was practically unchanged. The bath does not tend to lower the metabolism, and the heat production under these conditions is independent of the heat lost to the environment and therefore of the surface area.—(2) Body posture and minor muscular movements as affecting heat production. Oxygen consumption while standing was about 10 per cent. greater, and while sitting 2-3 per cent greater, than while lying down. Movements such as raising one arm or crossing the legs at intervals of less than 1 min also cause increases, and must therefore be proscribed while measuring basal metabolic rates.

NO. 2892, VOL. 115]

The Proscription of Darwinism.

ON March 23 the Governor of Tennessee signed a Bill which enacts that "it shall be unlawful for any teacher in any of the universities, normal schools, and all other public schools of the State which are supported in whole or in part by the school funds of the State to teach any theory that denies the story of the Divine Creation of man as taught in the Bible, and to teach instead that man is descended from a lower order of animals." This Act marks another important advance in the outlawry of Darwinism in American education. Tennessee is one of the most enlightened of the Southern States, but it has followed the example of five others. The last previous action, as stated in Prof. J. W. Gregory's "Menace of Colour," 1925, p. 74, was the unanimous decision last July of the State Education Committee of Georgia to refuse grants to any school or university which teaches the doctrine of evolution. The Legislature of Florida had earlier decreed, also unanimously, that it is "contrary to the public welfare for teachers paid by taxation to teach as a fact any hypothesis that links man in blood relationship with any lower form of life." A Bill with the same purpose was defeated in Kentucky by one vote only. Text-books of biology have been debarred from schools in North Carolina because they asserted a relationship between man and monkeys.

This proscription of Darwinism is the result of two main impulses—one religious, the other racial. The religious impulse is the more publicly expressed, and is doubtless the more influential. The Fundamentalists in the United States are as powerful as the Evangelicals were in England seventy years ago. The conclusions of "The Origin of Species" were denounced by Bishop Samuel Wilberforce to the British Association at Oxford in 1860; and his argument that they are inconsistent with Genesis had to be taken seriously. The support to that position had become negligible in England fifty years ago; but its survival in the United States is shown by the writings of Mr. W. J. Bryan, who has been thrice candidate for the Presidency, and was State Secretary in Wilson's cabinet. His theological books, including his "The Menace of Darwinism, and the Bible and its Enemies" (1921), "In His Image" (1922), and "Shall Christianity remain Christian?" (1924), are written in the frame of mind of Wilberforce; and as the Bishop repudiated an ape as his ancestor, Bryan represents Darwinism as adding insult to injury by insistence that man has descended, not from an American, but

from an African monkey. Bryan regards the Modernists as descending from Christianity to Atheism by successive adoption of seven grievous errors—"The Bible not infallible; Man not made in God's image; no miracles; no Virgin Birth; no Deity; no Atonement; no Resurrection." The multitude of those who make this descent is attributed to Darwinism. "The principal objection to Evolution," says Bryan, "is that it is highly harmful to those who accept it, and attempt to conform their thought to it Evolution does not ruin all who accept it, neither does smallpox kill all who take it. In fact only five per cent of those who take smallpox die of it. The spiritual mortality among evolutionists is greater than that." Bryan is probably right in his view that Darwinism has been the most effective factor in undermining belief in the literal inspiration of the Bible. Hence it is charged with being the main cause of the asserted decline in American morals and ethics. "Darwinism," says Bryan, "chills the spiritual nature and quenches the fires of religious enthusiasm." Fairhurst, in his "Atheism in our Universities," complains that their influence is ruinous; he declares that most of the students drink, half of them gamble, and only a tithe of them are interested in religion. A census is claimed to show that eighty-five per cent. of the students enter the Universities as Christians; the number of sceptics is doubled in the first year and trebled by graduation. Some Fundamentalists describe American society as "brought to the verge of ruin by a godless philosophy," which is based on evolution. Hence Bryan declares "Evolution is the Menace of Civilisation. It is the greatest menace to civilisation as well as to religion. Belief in God is the fundamental fact in society; upon it rests all the controlling influences of life. Anything that weakens man's faith in God imperils the future of the race."

Bryan's attempt to refute Darwinism is futile. It is, he says, "not science at all; it is guesses strung together." In support of its unscientific character he quotes "Dr. Etheridge, Fossiologist of the British Museum," and misrepresents modern authorities such as Bateson. The main charge against it is that it is "not only groundless but absurd and harmful to society," as it rests on the brute doctrine of survival of the fittest, which is said to encourage selfishness, to be fatal to the spirit of brotherhood, and to render certain the destruction of modern culture by international and industrial war. Men with such convictions naturally feel bound to prevent national funds being used in the spread of such pernicious doctrine. No teacher in a public school in the States would be permitted to teach that monarchy is superior to republicanism, and Bryan objects to public funds being used to sap national faith by "teaching daily what cannot be true if the Bible be true." He claims that men of science are a small minority and should not be allowed to use the public schools for the dissemination of their subversive dogmas.

The campaign against Darwinism also gains support from the objection to its evidence of a common ancestor for the Negro and Caucasian. The extent of this impulse is uncertain, but it is significant that the six States which have taken action against evolution are all in the south. On this question the Bible would appear to agree with Darwin; for did not Paul on Mars Hill declare that God "hath made of one blood all nations of men"? Some Americans avoid this difficulty by denying that negroes are descendants of Adam and claim that accordingly they are not men. The negro is a soulless animal at the head of the ape family! Believers in Noah's Deluge may fairly claim that the negro cannot have varied from the white stock as quickly as would be necessary to explain his appearance on earlier Egyptian records. If the negro be not a descendant of Noah, the Bible statements regarding "all men" are held not to apply to him.

The inter-racial difficulties in the southern states have certainly helped the anti-Darwinism agitation indirectly; for their educational backwardness and the poverty of one section of their people is due to the presence of the negro and to cheap negro labour. Recent statistics show that in two counties in North Carolina the white crofters and "renters" have a cash income per person of fourpence and sevenpence per day respectively; the corresponding classes of negroes earn a penny a day more. Families with such income cannot afford education, books, newspapers, doctors, or enjoy a reasonable standard of life. It is not surprising that they retain beliefs which, according to British notions, are decades out of date.

Bryan's eloquence and sincerity have made him perhaps the most powerful recent individual influence in American politics. But he has often failed to persuade his countrymen to adopt his policy. His present appeal for trust in the Rock of Ages rather than in "Ages of Rocks" may carry still further the educational outlawry of Darwinism; but it will probably fail in the end as completely as his famous appeal to the United States to adopt bimetallism "to save a world crucified on a Cross of gold."

Isostasy.

Isostasie und Schwеremessung: ihre Bedeutung für geologische Vorgänge. Von Prof. Dr. A. Born. Pp. iii + 160. (Berlin: Julius Springer, 1923.) 2·20 dollars.

THE variation from place to place of the intensity and direction of the force of gravitation is one of the comparatively few phenomena from which we can obtain some knowledge of the nature of the earth's interior. We owe to Pratt and Airy the demonstration in 1855 that, broadly speaking, different regions of the earth's crust balance one another, or, as it is now expressed, are in a state of isostasy; that the weight of mountain masses above the sea-level is compensated by a defect of density below them, and that ocean deeps are underlain by material of high density. But, whereas Pratt believed that the high places of the earth were the result of expansion of the material beneath them, Airy compared a mountain range to a log of wood floating in water, which it displaced and by which it was buoyed up. After nearly seventy years the same difference of opinion as to the real meaning of isostasy continues to persist.

In his treatise on isostasy and gravitation, Prof. Born has furnished us with a comprehensive exposition of the different methods of interpreting the results of gravity determinations and of the evidence that, in conjunction with geological data, they afford of the internal structure of the earth.

The intensity of gravitation at any point is accurately determined by observing the number of swings of a pendulum of known length during a period recorded by a chronometer, checked by astronomical observations or wireless time-signals. At sea other less exact means have hitherto been employed, but Dutch observers have now shown us that pendulum observations can be carried out in a submarine sunk to a sufficient depth to be practically free from wave action.

In the United States, numerous observations have been made by J. F. Hayford and William Bowie, of the U.S. Coast and Geodetic Survey, and the values obtained have been made the basis of calculations to show how far the principle of isostasy corresponds with the facts (U.S.C. and G.S. Special Publications, Nos. 10, 12, 40, 69, and 99).[1] In these the value experimentally determined, g, is compared with a calculated value, γ_c, based on the assumed value, γ_o, at sea-level[2] at a point directly below. To obtain g_c from γ_c the following corrections are made: (1) for difference of altitude; (2) for the attraction of the local rocks above sea-level, assumed to have a density of 2·67; (3) for the defect of density below sea-level necessary to compensate for the weight of the rocks above it. The difference $g - g_c$ is the isostatic anomaly of Hayford and Bowie. It is quite small, usually less than 0·05 of a dyne, but occasionally approaching a tenth of a dyne.

In calculating the effect of the compensating defect of density, they assumed that it was distributed uniformly below the point of observation from sea-level down to a depth known as the level of compensation, where the density and pressure were supposed to be everywhere uniform. Various depths were taken as the basis of calculation, and that which gave the lowest isostatic anomalies was supposed to be the nearest approximation to the level of compensation. On this basis Bowie obtained for mountainous areas a depth of 95 km. Calculations by Hayford based on deflexions in the direction of gravitation gave a depth of 97 km. Accordingly, Bowie assumed a depth of 96 km. in place of 113·7 km. previously adopted by the Survey. The depth of compensation derived from gravity data at low stations would be indeterminate, but there can, in my opinion, be little doubt that in plains and even plateaux a level of practically uniform density and pressure would be found at a much smaller depth, say 20 or 30 km.

The truth is that the idea of a level of compensation does not correspond to any important reality in Nature. It has no more significance than the level of the base of the largest and deepest of a number of icebergs. It seems obvious to a geologist that the amounts of compensation corresponding to different elevations are not to be represented by columns of equal depth and different densities, but by columns of approximately equal densities but varying depths In other words, the loftier the mountain range the deeper its foundations extend into the earth. Both mountains and their foundations appear to be mainly composed of similar comparatively light material, the "sial" (sedimentary and acid crystalline rocks), which in general rests upon and in mountain areas displaces more or less the heavier "sima" (basic material) below.

Isostatic anomalies are in some cases to be attributed to the support afforded to local elevations by the intrinsic strength of the earth's crust. This support is, however, given only for a limited time, except by rocks in the closest proximity and at a comparatively low temperature. Isostasy is a condition to which there is a constant approximation but which is never reached; for new developments, such as sedimentation or erosion, the formation or melting of ice-caps, and lateral compression or tension, are continually arising, which tend to destroy it, and then the process of

[1] Reference should also be made to the suggestive address to the Geological Society of America by the president, David White, on "Gravity Observations from the Standpoint of Local Geology" (Bull. Geol. Soc. Am., vol. 35, pp. 207-278, 1924). See, in addition, Andrew C. Lawson on the Geological Implications of the Doctrine of Isostasy, Bull. Nat. Research Council, vol. 8, part 4, pp. 24, 1924.

[2] By sea-level is meant the surface of the rotation ellipsoid adopted in 1924 by the U.S. Survey for the figure of the earth. As a matter of fact the computation is first made on the basis of the Helmert triaxial ellipsoid of 1901, with a subsequent correction (for U.S.A.) to the value of $g - g_c$ of − 0·008 dyne.

adjustment has to recommence once more. Other anomalies, perhaps the majority, can be best explained by the local occurrence near the surfaces, of rocks or deposits of a density differing in a marked manner from that assumed.

There is another method of reduction of gravity determinations, that of Bouguer, which throws more direct light upon the geological structure of the crust. The observed value, g, is reduced to what it would be at sea-level [3] if the whole of the rocks above (near enough to exercise any appreciable attraction on the point of observation) were removed This value is indicated by the symbol g''_o, and the difference $g''_o - \gamma_o$, where γ_o is the theoretical value at sea-level, affords infofmation of the depth to which the sial extends below it.[4] This is illustrated by an interesting map, by Kossmat and Lissner, of Middle Europe from Denmark to Sicily, showing the relation of $g''_o - \gamma_o$ to the great folds of sial, which form both the mountains above and their foundations below.

The whole subject of the relation of isostasy to mountain building, erosion, sedimentation, glaciation, and different types of earth structure is discussed in detail by Prof. Born. He makes the freest use both of the American determinations and of those of the Indian Topographical Survey, which will always remain a monument of the enterprise of Sir Sidney Burrard and his colleagues Prof. Born gives a detailed account of the work of Hecker and others in marine areas, and of the light thrown by the results obtained by Hecker Borras, Kohlschütter, and Krenkel on the nature of the rift valleys of Africa and South-western Asia.

Other subjects dealt with by Prof. Born are pseudo-anisostasy, the apparent departure from isostatic adjustment resulting from the attraction of rocks which do not form part of the column immediately below the point where gravity is determined, so that their weight is not included in that of the column; observations in oceanic volcanic islands—which usually show an excess of gravitational force due to a lag of isostatic adjustment; the relation of earthquakes to the want of isostatic adjustment; and generally the assistance afforded by observations of variations in gravitational force in the interpretation of the meaning of the present configuration of the world, and of the changes which have taken place in its past history.

Prof. Born's work is usefully supplemented by two memoirs from the Finnish Geodetic Institute.[5] Dr. Heiskanen has calculated the isostatic anomaly in a number of localities in Europe and the Caucasus. These calculations have been made, first on the same lines as those employed by Hayford and Bowie, and secondly on the Airy hypothesis that it is the *depth* of the lighter material that varies. From the isostatic anomalies obtained in this way it would appear that the latter hypothesis is more in accordance with gravity determinations than the former. This is the case even with the determinations in the United States with which Hayford and Bowie have worked. At the same time, the results obtained indicate that the thickness of the "earth's crust" (presumably that of the sial) below sea-level varies in different localities. Another important conclusion is that the idea that mountain ranges are not compensated separately but only in conjunction with their marginal depressions (Randsenken), and that the former are therefore under-compensated and the latter over-compensated, must now be abandoned. It has been supposed that the Harz and Riesengebirge are uncompensated. Dr. Heiskanen denies that this is the case. The detailed account of the results of the triangulation of South Finland is also of great interest. It contains (*inter alia*) a comparison of the deviations of the direction of gravity actually observed at the triangulation stations with those calculated from the orographical features and the compensation determined by the methods of Hayford and Bowie. The knowledge of the details of the topographical features is, however, at present too imperfect to allow any conclusions to be drawn.

Comparatively few contributions to gravitational data have come in recent years from the British Empire—with the conspicuous exception of India—though so much requires to be done within its limits. It is greatly to be desired that we shall in the future take a due share in this important work.

The recent meeting of the Geodetic Union in Madrid included a section devoted to isostasy. Unfortunately, the German and Austrian men of science, who have done so much to advance knowledge in this direction, were not permitted to attend. Their co-operation would have been all the more valuable because they have worked on lines somewhat different from those pursued in India and the United States. They have taken the fullest advantage of the information afforded by a century of geological research on the structure and past history of the earth's crust. It is absolutely necessary that geodesists and geologists should work in the closest association with one another if trustworthy conclusions are to be reached. JOHN W. EVANS.

[3] Here it is the surface of the "geoid," the level at which the sea would stand if admitted by canals to a point immediately below the point of observation. It differs but little from the triaxial ellipsoid of Helmert or the rotation ellipsoid of Hayford and Bowie.

[4] It would be better if the expression $\gamma_o - g''_o$ could be employed, where γ_o represented what would be the force of gravity at sea-level if the earth's crust below it were composed entirely of sima, for this difference would roughly correspond to the depth of the sial below sea-level.

Early Chemistry.

The Story of Early Chemistry. By Prof. John Maxson Stillman. Pp. xiii + 566. (New York and London: D. Appleton and Co., 1924.) 18*s.* net.

THE "noticeable gaps" which so many books are "intended to fill" are often discernible only to the authors. However, the absence of any book in the English language which deals adequately with the early history of chemistry will have been brought home very forcibly to all those whose business or inclination has led them to inquire into the available literature on this subject. It is therefore with genuine pleasure that we welcome the late Prof Stillman's thoughtful and scholarly treatise—a pleasure that is, alas, tinged with regret at the author's death just before the book was published.

As Prof. Stillman remarks in his preface, modern historians of chemistry have laid the emphasis upon the more recent development, so that it was very desirable to write a history of early chemistry which should incorporate the results of the investigations of Berthelot, Duhem, von Lippmann, Ferguson, Sudhoff, and other scholars. It may be said at once that the author has admirably accomplished the task—no light one—which he set himself. His book is brightly written, well balanced, and extremely accurate both in the main ideas and in the illustrative detail. No scientific library can afford to be without it, and this by reason of its intrinsic merits, quite apart from the fact that it has at present no competitors. A very valuable feature of the book is that, while avoiding a show of erudition, it gives full references to authorities for all important statements, and will thus prove useful to those who are engaged in research upon the history of chemistry.

In a field which extends from the beginnings of civilisation to the Chemical Revolution, no one man can hope to be infallible throughout. Prof. Stillman was especially interested in the fifteenth century, and in his account of this period he is seen at his best. He evidently has here a close acquaintance with the original sources, and his description is penetrating, sympathetic, and sound. For the other periods, he has relied chiefly upon the work of other scholars, but his judgment in the use of authorities is seldom at fault and is generally very shrewd. Particularly good is the first chapter, which deals with the practical chemistry of the ancients. On the question of the origin of chemistry he is not so trustworthy, and seems to be quite unaware of the theory of the growth of civilisation now so warmly advocated by Prof. Elliot Smith and Mr. W. J. Perry—a theory which has a very direct bearing upon the problem of the birth of chemistry.

The theories of the ancients upon matter and its changes (Chapter iii.) are described adequately but by no means comprehensively. Justice is scarcely done to the Greek thinkers, although we are pleased to see the stress which Prof. Stillman lays on the *Timæus*, the influence of which upon medieval chemical thought was very considerable.

That the description of chemistry in Islam is thoroughly unsatisfactory is no reflection upon Prof. Stillman. From the published work on this subject which he had at his disposal, he could not possibly have produced a better account than he has done. He might, however, have got an Orientalist to look through his transcriptions of proper names, and thus have avoided such needless errors as *Moaonia* for *Mu'āwiya*, *Oneeyade* for *'Omayyad* (p 175), and *Eç-Confy* for *Al-Sūfī* (p. 176). These are details which should receive attention in the second edition.

In dealing with the seventeenth century, again, Prof. Stillman has almost entirely neglected the brilliant series of chemists at the Jardin des Plantes—Béguin, Davidson, Glaser, and others—who did much to prepare the way for the great Lemery. Taken as a whole, however, the book is a worthy example of modern American historical scholarship, and may justly claim to rank with Cajori's "History of Physics," Smith's "History of Mathematics," and Lynn Thorndike's "History of Magic and Experimental Science."

E J. HOLMYARD.

On Being Born and Well Born.

Genetics and Eugenics: a Text-Book for Students of Biology and a Reference Book for Animal and Plant Breeders. By Prof W E. Castle. Third edition. Pp. viii + 434 + 60 plates. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1924.) 12*s.* 6*d.* net.

THE fact that this third edition is subdivided into forty-two chapters, six of them new, may provide an indication of the variety of the topics which interest the geneticist. In American literature this book, not the least remarkable feature of which is its cheapness, occupies the position which Punnett's "Mendelism" and Thomson's "Heredity" together hold on the eastern side of the Atlantic: it offers to a very wide public an introduction to genetical fact and theory and some notion of the applications of the science in agricultural and sociological endeavour. Associated with this edition there is a laboratory manual which outlines a very useful half-year's elementary experimental course in genetics. Most of the experiments demand the employment of *Drosophila melanogaster*, but this does not make the manual unsuitable, for there is an adequate supply of this

unrivalled experimental material now available in Great Britain as well as in the United States.

The book is not meant to be a text-book for a class in genetics: the intention of its writer is that it should be a text-book for students of biology and a reference book for animal and plant breeders. The characteristic stamp of the personality of the author is too deeply impressed upon its pages, in our opinion, for the book to be the ideal introduction to the subject for the student of general biology, and the value of those chapters which deal with the phenomena of inheritance in the different species, great as it is to-day, must quickly become depreciated in view of the recent appearance of such monographs as are included in "Bibliographia Genetica" To the geneticist, however, the book is most attractive, for in no other form could the views of the author, who, both as teacher and as experimenter, has contributed so notably to our knowledge of genetics, be so attractively placed on record

There is abundant evidence in this book that Prof. Castle knows his rodents: that he knows his fowl as well is not so certain. On p 77, for example, he submits that "one condition on which the crowing instinct of cocks rests is the production in its body of substances produced by the testis." While it is certainly true that the gonadless fowl does not crow, it is equally true that a cock castrated and with an ovarian implantation will do so, and that a hen, perfectly normal in structure and functioning in every way as a hen, will, in the protracted absence of the male, crow most vigorously, though her voice may not be so full of challenge On p. 300 it is stated that "fowls of both sexes will develop the same plumage characters, viz. the full plumage of normal males, if no secretions interfere." It is true that the plumage of the capon and the poularde is as that of the normal male in colour and structure, but that of the gonadless bird is far more luxuriant in its growth and far looser in its texture than that of the functional cock. We think also that Prof. Castle accepts with too little reserve the suggestion that the "luteal" cells in the ovary of the hen and in the testes of the henny-feathered cocks are the source of an internal secretion which inhibits cocky-feathering. The weight of modern opinion is quite opposed to this contention.

In discussing the relation of Mendelism to mutation and evolution, the author submits that the Mendelising characters of the domesticated mammals consist very largely of such economically unimportant qualities as coat-colour, hair-length, or hair slope, and that the really valuable characters, such as those of size, proportion, early maturity, milk-yield, butter-fat content, wool, and fecundity, are not typically Mendelian in their inheritance, but are examples of blending. We were about to debate the question as to what exactly the author regards as typically Mendelian when a few lines further on we found that Prof. Castle acknowledges that very likely the inheritance of these complex characters of economic importance is also Mendelian. He provisionally accepts the conception of multiple factors, but is mistaken in assuming that such a theory demands that there shall be no dominance.

Forty-seven pages are devoted to eugenics. In a book such as this, written for such a public, it is indeed desirable, we think, that an outline of the facts of human inheritance should be included, for the determination of the extent to which mankind is subject to the general principles of genetics is most certainly a biological problem and one that should be brought to the notice of the student of biology. To determine how far these principles are socially controllable, on the other hand, is a problem for the sociologist, and Prof. Castle, a geneticist, makes no serious attempt to deal with it. However, he closes the book with a somewhat pessimistic chapter on "The Possibility and Prospects of breeding a better Human Race," in which he calls largely upon the conclusions of Prof. Cattell, drawn from the latter's study of the families of the one thousand leading men of science of the United States

We commend this book especially to those who enjoyed and so ceaselessly quote "Eugenics and other Evils" They will find therein such conclusions as the following reached by one who is qualified to speak with some authority. The normal unperverted instincts of the average man have a distinctly eugenic trend. Cupid is a safer guide in matrimony than a licensing board. Racial crossing among men, as among domesticated animals, is biologically beneficial within limits. This mixture of elements not too dissimilar, provided the social heritage is not unduly disturbed, is on the whole beneficial. Biologically the human race can be improved only by improvement of the germplasm. If, as seems probable, acquired characters are not to any considerable extent inherited, then environmental agencies affect man chiefly culturally, not biologically. Practically we are limited to such eugenic measures as the individual will voluntarily undertake in the light of present knowledge of heredity It will do no good, but only harm, to magnify such knowledge unduly, or to conceal its present limitations. We should extend such knowledge as rapidly as possible but not legislate until we are very sure of our ground.

With such conclusions all geneticists will agree. This being so, it is as unjust to blame the geneticist for the mishandling by the lawmaker or enthusiastic sociologist of the facts that he discloses, as to hold the chemist responsible for the adaptation by others of the results of his research to the purposes of war. F. A. E. C.

Our Bookshelf.

Meteorological Office: Air Ministry. British Rainfall, 1923. The Sixty-third Annual Volume of the British Rainfall Organisation. Report on the Distribution of Rain in Space and Time over the British Isles during the Year 1923, as recorded by about 5000 Observers in Great Britain and Ireland. (M.O. 269.) Pp. xxii+256. (London: H.M. Stationery Office, 1924.) 15*s.* net.

AN analysis of the rainfall for the year is given covering the whole of the British Isles. The year was decidedly wet, being the wettest year since 1916 except in Ireland. The largest excesses occurred in the west. There were more days with rain than in any other year since comparable statistics began in 1903. The average monthly rainfall during the year over the British Isles as a whole varied from 6·5 in in February to 1·4 in in June; only two months, March and June, showed considerable deficiencies. February 1923 is said to be probably the wettest February on record. Rainfall maps for the British Isles are given for each month, as well as for the summer and winter seasons and for the year.

Examples of dramatic weather during the year are given, these occasioning floods in different parts during July and November. Serious floods occurred at Carrbridge in Inverness-shire on July 8, and on the night of July 9-10 a memorable thunderstorm was experienced, and about 7000 flashes of lightning occurred during 6 hours in London and the suburbs, while 4·55 in. of rain fell in Sussex.

A special article is given on the fluctuations of annual rainfall; a comparison is made of different groups of 35 years in the period 1868 to 1921, and also with the standard period 1881 to 1915, the 35 years' average in general use in the Meteorological Office. The averages for the different periods of 35 years show a good general agreement. C. H.

Bearbeitung einheimischer Tiere. Herausgegeben von Prof. Dr. E. Korschelt. Erste Monographie: Der Gelbrand *Dytiscus marginalis* L. Erster Band. Pp. v+863. Zweiter Band. Pp. vii+964. (Leipzig: Wilhelm Engelmann, 1923–24.) n.p.

THESE two bulky volumes constitute the first of a series of monographs dealing with the fauna of Germany, the subjects selected forming a series of "types" of the animal kingdom for study in the university courses. Probably no better subject for the study of insect structure and metamorphosis than the "Gelbrand" could have been selected. Not only is the Great Water-Beetle hardy and easily kept in captivity, with a comparatively rapid metamorphosis, but it illustrates remarkably well the specialisation of a primitive type in response to the special circumstances of its environment.

Vol. 1 deals with the skeletal system, its appendages and sense organs, and the nervous, muscular, respiratory and circulatory systems of both adult and larva. Vol. 2 completes the structural treatment with the consideration of the fat-bodies, and the alimentary and reproductive systems, passing on to development and metamorphosis and various aspects of its bionomics. Finally, there are two very interesting chapters on its early literature and systematics. After each chapter is given a very full bibliography for that particular part of the subject. Both volumes are abundantly supplied with excellent illustrations.

Owing to unavoidable delay in the appearance of the work as a whole, it was felt that the results of certain pieces of research should be separately published in anticipation, so that some of the chapters in the complete work are practically reprints of papers previously published by Dr. Korschelt or his collaborators.

In view of the great attention to detail evidenced throughout the work, it is a little surprising to find no mention of the "pigment-spot" on the wings, an organ that has recently been claimed to serve a stridulatory function, neither, indeed, do we find any reference to the well-known stridulatory powers of the insect, and but the briefest mention of Finkler's experiments on the transplantation of the head from one individual to another.

An index would have facilitated reference, though its lack is to some extent compensated for by a very full list of chapter headings and subheads for each volume.

A History of Bleaching. By S. H Higgins. Pp. viii+176+9 plates (London Longmans, Green and Co., 1924.) 10*s.* 6*d.* net.

AN investigation into the early history of any industry is of much interest, and may be of considerable value in throwing light on modern practice. Sometimes, as in the case of the bleaching of textiles, fairly detailed records of ancient processes are found, but it is not possible to compare the results obtained then and now, because a fabric bleached even one hundred years ago inevitably will have become more or less discoloured. On the other hand, there are many cases in which we can examine the results of ancient craftsmanship, but have no knowledge of the methods by which they were produced.

The demand for a "perfect" white on cotton, linen, and other textiles is comparatively modern. From an æsthetic view-point, the slightly brownish or greyish tint of white, which must have been the ultimate product of the bleacher before the introduction of chloride of lime, is more pleasing than the more luminous bleached white of to-day, which is probably the outcome partly of trade competition and partly of the requirements of some modern methods of textile printing.

The development of bleaching processes has taken place along two main lines, chemical and mechanical, and Mr. Higgins in his book traces the improvements due, in the first place, to the increase of chemical knowledge, and secondly, to the necessity of dealing with larger quantities of material. Chemical engineering received its early stimulus through the exigencies of the alkali industry and its offshoots, and thus early turned its attention to bleaching and the allied industry of calico printing; the mechanical developments in dyeing processes coming much later.

With the single exception of the introduction of bleaching powder about the beginning of the nineteenth century, there has been no fundamental change in bleaching processes since a very early period. The magnitude of the industry at the present time is indicated by the statement in the last paragraph of the book that about 2,000,000 *miles* of cloth are bleached

annually in Great Britain, a statement which may be approximately accurate if the amount of cloth which is partially bleached as a preliminary to dyeing or printing, is included. W. M. G.

Liverpool Marine Biology Committee. L.M.B.C. Memoirs on Typical British Marine Plants and Animals. 26: Botryllus. By E. Catherine Herdman. Pp. xi+40+6 plates. (Liverpool: University Press of Liverpool, Ltd.; London: Hodder and Stoughton, Ltd., 1924.) 4*s.* 6*d.*

THE author of the present volume, on the compound Ascidian Botryllus, is a daughter and pupil of the late Sir William Herdman, who himself, twenty-five years ago, wrote a description of a simple ascidian as the first volume of the series to which this is the latest addition

The editors of the series explain in a preface the interest attaching to Botryllus, and its advantages as a representative of the group to which it belongs. Miss Herdman's account, which follows, is carefully done, well arranged, clearly written, and excellently and fully illustrated by means of six plates, one of which is in colours. Besides the description of the anatomy, the author gives sections on embryology and development, and on the formation of the colony, as well as paragraphs on such subjects as coloration and the systematic position of the family. There are interesting references to the germ-layer theory in relation to the formation of the organs in the asexually produced blastozooids; to the mode of capture of the food particles; to the functions of the neural gland and dorsal tubercle; to the cause of the curious recurring alternations in the direction of the blood-flow; and to the special functions of the colonial vascular system. It is, however, to be regretted that in a book which the editors hope "will be found of value by students of biology in laboratories and in marine stations, and will be welcomed by many others working privately at marine natural history," the author has not included some account of the most suitable methods of examination.

The Place of Partial Differential Equations in Mathematical Physics: Being a Course of Readership Lectures delivered at Patna University in 1921. By Prof. Ganesh Prasad. Pp. iv+49 (Patna: Patna University, 1924.) n p.

IN the six lectures before us, Prof. Prasad gives an interesting account of the part played by partial differential equations in dealing with vibratory phenomena, conduction of heat, gravitational attractions, electrostatics, magnetostatics, hydrodynamics, electrodynamics and the theory of electrons Since D'Alembert's discovery in 1747 of the equation $\ddot{y}=c^2y''$ arising from the motion of a vibrating string, the study of natural phenomena by mathematical physicists has led them to certain standard types of differential equations. The essential difficulty in finding the solution of such a differential equation lies in fitting it to specified boundary conditions If we have an initial stage of heat given by

$$f(x)=x \text{ for } x>0, f(x)=-x \text{ for } x<0,$$

the first and second differential coefficients are non-existent at the origin and the equation of linear conduction, $\partial v/\partial t=\partial^2 v/\partial x^2$, is meaningless there. An unlimited number of similar cases can be constructed. Though partial differential equations are quite serviceable for most ordinary purposes, in a rigorous treatment they have to be relegated to a secondary place. It is quite possible that at some future time differential equations will appear as but crude instruments and be discarded in favour of the more powerful and more refined integral equations.

Linear Integral Equations. By Prof. W. V. Lovitt. Pp. xiii+253. (New York: McGraw-Hill Book Co., Inc.; London: McGraw Hill Publishing Co., Ltd., 1924.) 15*s.* net.

THE subject of integral equations has been much neglected in university teaching in Great Britain, partly because of the scarcity of text-books suited to the needs of the normal student of mathematics. In addition to a clear exposition of the theory, to carry conviction what the student requires above all is a number of particular examples and applications. The works of Bôcher (1909) in English, Volterra (1913) in French, and Kneser (1922) in German are available but are scarcely in general use.

Prof. Lovitt has produced a very readable book on this very important branch of mathematical study. The discussion, confined to those equations which are linear and in which a single integration occurs, does not deal with equations involving several independent variables, systems of integral equations or integro-differential equations. The author covers, however, in systematic manner the general theory of linear equations, exemplifying the points as they arise by a large number of particular cases and applying the methods to problems in differential equations, the calculus of variations, Neumann's and Dirichlet's problems, and to a series of cases of vibration. There is nothing very new in substance in the book, but it is eminently readable and very well produced.

In the High Himalayas: Sport and Travel in the Rhotang and Baralacha; with some Notes on the Natural History of that Area. By Hugh Whistler. Pp. 223+16 plates. (London: H. F. and G. Witherby, 1924.) 15*s* net.

MR. WHISTLER'S book treats of sport and travel in a remote part of the Himalayan districts of the Punjab, Kulu, Lahul, and Spiti, of which the last is geographically part of Tibet though politically a district of India. The chapters dealing with it are of most interest since the country is almost unknown, but the whole book contains a great deal of valuable geographical and natural history material, including a chapter on birds. There are some fair illustrations and an adequate map.

Ross and Cromarty. By Prof. W. J. Watson. (Cambridge County Geographies.) Pp. xi+140. (Cambridge: At the University Press, 1924.) 3*s.* 6*d.*

PROF. WATSON has added a useful volume to the series of county geographies. The book is especially interesting on the human side, though with commendable restraint his section on the people, race, and dialect occupies only two and a half pages. We notice that he describes the Celts as members of the Nordic race, without actually using that term, and to this stock he attributes some of the fair-haired people of this highland area.

Disintegration of Atomic Nuclei.

SINCE the discovery that high speed protons are emitted from the nuclei of a number of light elements by a close collision with an α particle, it has been a matter of great interest to understand the mechanism of these collisions and particularly the fate of the bombarding α particle. Dr Chadwick and I have shown that the protons are emitted in all directions relative to the bombarding particles, but with greater velocity in the forward direction. This difference of velocity was ascribed to the effect of recoil of the nucleus, and assuming that the law of conservation of momentum, but not of energy, holds in such collisions, we were able to calculate from the experimental data the distribution of momentum between the particle, proton, and nucleus after the collision. These calculations showed that the velocity of the escaping α particle was small for nitrogen, sodium, aluminium, and phosphorus, but considerable for boron and fluorine. Unfortunately, on account of the small number of particles, it is difficult to determine accurately the velocity of the proton in different directions, but, with accurate data, this method should prove useful in throwing light on the distribution of momentum amongst the particles concerned in the collision.

The number of collisions leading to the escape of the proton increases rapidly with the velocity of the impinging α particle, and in the case of aluminium we could observe few, if any, protons when the bombarding α particle had a range less than about 5 cm. The most direct method of studying the results of these collisions is to obtain actual photographs of the tracks of the particles by the well-known cloud method. From the data obtained from our investigations with nitrogen, it seemed probable that about one α particle in 40,000 would liberate a proton when using a source of the swiftest α rays available, namely, thorium-C, which emits particles of range 8·6 cm. in air.

The laborious task of photographing in two perpendicular directions the tracks of about 400,000 α particles was undertaken by Mr. Blackett in the Cavendish Laboratory, using a modification of Shimizu's method. The results of this investigation have been recently published in the Proc. Roy. Soc., 107, p. 349, 1925. In addition to a number of collisions of the α particle with a nitrogen nucleus which obeyed the ordinary laws of an elastic collision, Blackett observed eight forks in all where these laws were not obeyed, and these he ascribed to collisions involving the liberation of a proton. The fine track of the proton was clearly visible, also that of the recoiling nucleus, but there was no sign of a third track to be expected if the α particle escaped after the collision. He concluded that the α particle is captured by the nitrogen nucleus under these conditions, and that in consequence the mass of the recoiling nucleus should be 17 and its charge 8—namely, an isotope of oxygen. He observed that the tracks were coplanar, indicating the conservation of momentum, and found the velocities of the proton and recoiling nucleus to be in fair accord with this assumption. Mr. Blackett hopes to examine in a similar way a number of other active elements to see if a similar process takes place.

It is not my intention here to discuss the bearing of these results on the mechanism of disintegration, but rather to direct attention to other results and suggestions in connexion with this important problem. In 1923, Prof W D. Harkins and R. W. Ryan (Journ. Amer Chem. Soc., 45, p 2095) photographed about 21,000 α ray tracks in air, using the Shimizu method, and amongst other observations recorded a photograph of a collision in which the α ray track broke into three distinct branches—indicating a disintegration in which two high speed particles appear in addition to the recoiling nucleus. My attention has recently been directed to another interesting photograph in air by a similar method, recorded by M. Akiyama (*Jap Journ. Phys.*, 2, p 272, 1923), which also shows three branches The proton in this case is expelled nearly in the backward direction, and two other tracks ascribed to the escaping α particle and recoiling nucleus are clearly visible. It is, of course, difficult to reconcile these photographs with the eight obtained by Blackett in which no third branch has been noted , but it may prove significant that the collisions photographed by Harkins and Akiyama appear to have occurred when the α particle has lost a good deal of its range It is obvious that there is still much work to be done to clear up these difficulties.

In view of the evidence obtained by Blackett of the capture of an α particle, I have thought it of interest to bring to the attention of readers of NATURE two clear statements of the likelihood of such a capture in a collision which leads to the expulsion of a proton In a discussion of a paper on the structure of the atom, read by me before the Solvay International Institute of Physics in 1921 (Rapports et Discussions du Conseil de Physique de Bruxelles, p. 68, published 1923), a reference to this question was made by Prof. J. Perrin. A selection of the remarks made by him will be given in full, as the above publication may not be generally accessible to readers of NATURE:

M Perrin.— . . . " Les expériences mêmes de M. Rutherford semblent prouver qu'il faut renoncer à cette idée d'un simple choc. Le projectile α, en raison de sa grande vitesse, et malgré une très forte répulsion électrique, peut arriver, très ralenti, au voisinage immédiat du noyau A ce moment, une ' transmutation ' se produit, consistant probablement en un réarrangement intranucléaire, avec capture possible du noyau α incident (car nous ne savons pas ce qu'il devient), émission du noyeau d'hydrogen formant le rayon H observé, et peut-être encore avec d'autres projections moins importantes. Il n'y a aucune raison, dans cette façon de voir, pour que le projectile H émis ' se souvienne ' de la direction du choc initial ni pour que son énergie (empruntée pour une part à l'énergie électrique intranucléaire) soit inférieure à celle du projectile incident.

" Si, par exemple, le noyau d'aluminium heurté capture le projectile α et n'émet pas d'électrons, il reste, après l'émission du projectile H, un atome dont la masse est (27 + 4 − 1), soit 30, et dont le numéro d'ordre est (13 + 2 − 1), soit 14, donc un atome isotope du silicium. D'autres hypothèses seraient d'ailleurs faciles."

A suggestion of a similar kind has also been made by Pettersson and Kirsch. They forwarded to me, in June 1924, a short paper intended for publication in which they gave a brief statement of preliminary experiments on the number and nature of the particles liberated from carbon and aluminium at an angle of about 135° with the bombarding α particles. From these data they suggested that the α particle might be captured in collisions in which the proton is liberated. A paper including a statement of their

views on this question was given at the Versammlung Deutscher Naturforscher und Arzte at Innsbruck in August and published in the *Physikalische Zeitschrift* (25, No 22, p 588, 1924)

We must await the results of further detailed experiments to see how far such observations of scattering throw definite light on the problem of the mechanism of a disintegrating collision. It seems clear, however, that a large amount of careful quantitative work as well as a great number of photographs of α ray tracks will be required before we can hope to obtain detailed evidence of the mechanism of such collisions and of the fate of the bombarding α particle for all the " active " elements.

Cavendish Laboratory, Cambridge.

The Source of Stellar Energy.

I AM glad to have drawn so interesting a letter from Prof. Eddington as appears in NATURE of March 21. I cannot, however, agree with him that the present position is one of " an almost hopeless deadlock," and neither do I agree with his criticisms of my scheme (NATURE, Feb 28), by which a star consists of a mixture of different types of destructible matter which spontaneously dissolve into radiation at different rates, the rate in each case being unaffected by physical conditions of temperature and pressure. The process imagined by me was in fact analogous to radioactive decay except that the end product is radiation instead of other forms of matter

Prof. Eddington considers that under this scheme the stars would be unstable. A star which in some way increased its rate of generation of energy would expand and this expansion would, he says, lessen the rate at which it was able to radiate its energy away. But why ? The expanded configuration is not one of equilibrium and I cannot see that we have any knowledge as to the corresponding rate of radiation. *A priori* we would certainly expect that the star's first move, when it found too much radiant energy accumulating in its interior, would be in the direction of getting rid of more radiation, not less, as Prof. Eddington asserts. If so, Prof Eddington's argument collapses entirely It may be remarked that if the argument were sound and instability were proved, we could only restore stability by supposing that a decrease in a star's density and temperature *decreased* its spontaneous generation of energy, whereas in actual fact it is the stars of lowest density and of lowest internal temperature which radiate the most energetically

My suggestion that when a star breaks up its ingredients are not fairly distributed between its constituent parts is criticised in the light of some conclusions Prof Eddington has drawn from a certain recently published mathematical theorem May I here merely state that in my opinion this theorem is entirely fallacious ? I hope to justify this statement in print very shortly.

My scheme certainly requires " that the rate of emission of radiation by the star shall be very largely dependent on its previous history." In actual fact considerable ranges of luminosity are shown by stars of identical mass. These I should attribute to differences of birth and previous history, and it may be possible to infer something as to the past histories of the stars from these ranges. Prof. Eddington considers that the observed range is too small, but does he know enough of the past history of different stars to say how large a range ought to be expected ? He discusses two hypothetical stars born originally with masses 12 and 3, but is there any reason for thinking that stars can be born with so great a disparity of mass ? I have, of course, to admit that in time a real difficulty may appear here, but at present its existence is not proven. To my mind the present difficulty lies in precisely the opposite direction ; it is to account for the tendency towards equality of mass which appears in the two components of a binary as its evolution proceeds

I find it difficult to understand the advantages of the hypothesis which Prof. Eddington offers as an alternative to mine. He supposes certain destructible types of matter to be formed at a rate which depends on temperature and density. Their rate of spontaneous dissolution does not depend on the temperature and density at the instant, so that the rate of generation of radiation depends only on the total amount of destructible matter present in the star, which in turn depends on all the temperatures and densities of the past. The radiation, in fact, represents a sort of integral of the past temperatures and densities. As regards stability his stars are in the same position as those of my scheme, while as regards dependence on past history they seem to be worse off.

Any variation, either of creation or destruction of matter, with temperature and density ought almost certainly to be in the direction of higher activity accompanying an *increase* of density and temperature, whereas in actual fact the (internally) hot dense stars radiate little and vice versa. If Prof Eddington insists on any sort of dependence on density and temperature, he must not only, as he says, " admit exhaustion-effects also," but must actually admit more exhaustion-effects than are required by my own hypothesis—unless indeed he can prove that high temperature and density inhibit radiation.

Relation of Light to Bird Migration and Developmental Changes.

THAT light is a factor of prime importance in the inauguration or stimulation of bird migration, has been suggested by many authors from the days of Seebohm onwards. While many of the suggestions will not bear close investigation, at least one very attractive view has been put forward by Sir E. Sharpey-Schafer. In an address delivered some years ago to the Scottish Natural History Society [1] he makes the following comments, " . . . the regularity with which migration occurs, indicates that the exciting cause must be regular. There is no yearly change, outside the equatorial zone, that occurs so regularly in point of time as the change in the duration of daylight On this ground this may well be considered a determining factor in migration, and it has the advantage over other suggested factors that it applies to the northerly as well as to the southerly movement." He says further " That it [migration] is a result of developmental changes in the sexual organs is improbable."

Evidently inspired by the work of the botanists Garner and Allard on what they have termed " photoperiodism," an American author [2] has lately revived this theory and has, apparently independently, come to the same conclusion as Sir Edward with regard to the absence of relation between developmental changes in the reproductive organs and migration.

On purely theoretical grounds it has always seemed to me that if the waxing and the waning of the days really in any way affect the migratory impulse, they must produce their effect through the gonads. This

[1] " On the Incidence of Daylight as a determining Factor in Bird Migration," E. A. Schäfer, NATURE, vol. 77, pp 159-163 (December 29, 1907).
[2] " Is Photoperiodism a Factor in the Migration of Birds ? " G. Klein, *Auk*, vol. 41, pp. 439-444.

is not the place for theoretical discussion, and I merely wish to record an experiment that has just reached completion. Other corroborative work is still in progress and a critical histological examination of the experimental and normal material yet remains to be undertaken.

In September of last year I trapped a number of Juncos (*Junco hyemalis*) on their southward migration to the Middle States. These were turned into two large open-air aviaries removed from shelter of any kind. One, into which about a dozen birds were put for the experimental work, was fitted with two 50-watt electric lights. The other housed controls. Commencing on October 2, the lights were turned on at sunset (that is, while the birds were still fully active) and kept on until five minutes after dark. Each day afterwards the time was lengthened by five minutes. Taking into consideration the differences in time of sunrise, the birds thus got about three minutes longer illumination daily On account of the fact that they went to roost at their usual time on the first day in spite of the glaring lights, and that attempts at educating them to keep awake were never wholly successful, and less so with some individuals than with others, it has proved impossible to estimate the effective light increases For the same reason there is lack of uniformity in the results obtained

Elimination of the warmth factor was unexpectedly successful—thanks to a severe winter—the lowest temperature to which the birds were exposed being 50° below zero (Fahrenheit).

Birds were killed at intervals of approximately two weeks, with the following results :

Dates of Killing.	Number Examined.	Size of Testes [a]
Oct 15	1	0·50 × 0 48
(A wild bird killed same date		·60 × ·60) [c]
Oct. 29	1	·44 × ·41
Nov. 13	1	·45 × ·53
Nov. 26	1	·60 × ·44
Dec 11	1	·80 × ·79
Dec. 27 [b]	2	(*A*) ·90 × ? (Part of ribbon destroyed)
		(*B*) 1·80 × 1·54

Catastrophe overtook my control birds and I had to find substitutes. Through the kindness of the Museum of Vertebrate Zoology, University of California, I have been receiving fixed gonads of Juncos (a closely related species of approximately the same size) wintering in the Berkeley district These are not strictly comparable with mine, therefore, but the samples include birds taken at intervals from November to early January. In spite of the California climate, the January testes are minute. My solitary female, killed also on December 27, as compared with the early January females from Berkeley, has an ovary two to two and a half times as large and with conspicuous follicles.

The two males and the female killed on December 27 were kept indoors for their last week at an average temperature of about 40°. (Their drinking water froze one night.) The marked difference in the size of the testes of the two males may probably be accounted for by their habits. *A* went to roost, in spite of the lights (the birds were together in the same cage) about an hour to an hour and a half each night before *B*. The female kept the latter company. *A* sang a good deal ; *B* incessantly All the birds were in excellent condition when killed.

It would, therefore, appear that whatever effect daily increases of illumination may or may not have on migration, they *are* conducive to developmental changes in the sexual organs Comparison of the normal material from Riviera-like California with the experimental product from Alberta further suggests that favourable light conditions are more potent in this respect than favourable temperatures.

WILLIAM ROWAN.

11142 86th Ave., Edmonton, Alta., Canada, January 28.

[a] The whole series of testes was sectioned at 6μ. The first column indicates the greatest diameter of the largest section in each series in millimetres. The second is arrived at by adding the total number of sections for each series and multiplying by 0·006.

[b] The testes of this bird, still on migration, had not yet reached the winter minimum and this accounts for their large size. Diminution in size during the initial stages of the experiment is very marked.

[c] *A* was an adult bird ; *B* a bird of the year.

The Mortality of Plaice.

IT is most valuable to have Dr. Wallace's authoritative opinion (NATURE, March 7) that the scarcity in the North Sea of male plaice more than 8 years old is due to their own physiology and not merely to selective fishing. I suggest, however, to Dr Wallace that this is no evidence of senile death, but of what we may conveniently call *parental* death "The *rapid* decline in the relative number of males just after maturity" (the italics are Dr Wallace's) indicates that death is a consequence of their last and most productive spawning, and Atkinson's Barents Sea Statistics (Table II.) seem explicable only if ♀ of the males there die after first spawning We know that fresh-water eels spawn once and die, the conger also (Cunningham, Journ M B A., vol 2, p. 31) spawns once and dies, and Child ("Senescence and Rejuvenescence," p. 302) states the same of the American salmon, adding, "the organism is undoubtedly in an advanced stage of senescence when sexual maturity is attained" Minot and Child, by the great importance of their work, have permanently changed the meaning of the word "senescence" to signify progressive diminution in rate of metabolism, and they have shown that "senescence" starts at a maximum in the dividing ovum and falls rapidly with advancing age. I would plead that "senility" be still left in its original meaning to designate the negative growth in man which begins after full sexual maturity, and the like phenomenon where it is found to occur in other organisms ; so that we have terms in which it is possible to discuss whether "senility" be really merely the latter stage of "senescence." The death of a fish after spawning in the fulness of its power bears little resemblance to senile death, but is comparable to death of the spore-case when the spores are discharged, or of the wheat-stem when the grain is fallen ; sexual reproduction primitively destroys the parent The whole dividing protozoon disappears and the whole is utilised, but in metazoa a continually larger and more important somatic residue is wasted in death : in the conger, figures cited by Cunningham indicate that the heaviest roes approach to half the total weight, the residual body unutilised being therefore, at the lowest, equal in weight to the matricidal ovaries. So in many groups this loss of capital to the species is gradually avoided ; the spent British salmon succeeds in returning to the sea and building up again in a year or two strength sufficient for a second spawning ; the descendant of annual flowering plants takes on the biennial habit

The hypothesis of potential immortality applies only to those plants and animals (of which, I still suggest, the female plaice may be one) which have completely lost the originally universal liability to parental death and have become perennial; and botanical

friends tell me that they know no evidence of senility in perennial root-stocks or 5000-year-old trees. My suggestion is that we have no evidence of senility in the female plaice, and that senility is not an inherent quality of protoplasm, but the consequence of a mechanism for the preservation of specific size. The plaice has no specific size, and therefore, when in the female growth is not ended by parental death, no mechanism for the limitation of growth is evolved and there is no senility

Among animals which produce numerous young there is more reason for the female to attain the perennial habit than for the male, since a female plaice must grow for many years before she is large enough to produce as many ova as one eight-year-old male can fertilise. Even human curves of growth and senility indicate that in these aspects the male and the female are different animals. Looking at other groups, it becomes clear that no conclusion as to the gradient of life in one sex can be formed from observation of the incidence of death in the other: the queen-bee's life-history bears little relation to that of a drone, the longevity of the female spider is not measured by that of the consort she devours, and the female barnacle, *Scalpellum ornatum*, is associated with a succession of short-lived epizoic males.

I suggest to Dr. Wallace that we have as yet no evidence of senility in plaice, but of parental death for the North Sea male on perhaps the third spawning, at a body-weight of some 700 grams. There is an unproved possibility of parental death for the female on reaching some very much larger size at which her ovaries would bear a lethal ratio to her body-weight; this we may guess, on the analogy of the conger, might be when the ovaries form about one-half the total weight. If the ratio of ovary-weight to body-weight continue to increase according to the formula $y = x^k/400$ (NATURE, January 31, p. 155), the ovaries would be one-half the weight when the plaice attains 6000 grams if $k = 1{\cdot}61$, and when it weighs 16,000 grams if $k = 1{\cdot}55$. (The largest plaice recorded, *fide* Cole and Johnstone, weighed 6800 grams.) If, on the other hand, as the fish grows larger k diminishes, and reaches 1·0 at a constant ratio of ovary-weight to body-weight which allows the residual body to recover after spawning, then the female plaice has lost liability to parental death, while it has assumed neither specific size nor the senile death which is its consequence.

GEO. P. BIDDER.

Cambridge, March 12

The Propagation of Radio Waves over the Earth.

IN NATURE of March 7 there are two letters dealing with the subject of the transmission of electric waves over the earth's surface. Prof. Appleton has given some results which indicate that very marked interference effects occur at night. So far as I understand, he has suggested an interpretation of the experimental results in terms of the simple theory in which the maxima and minima of received intensity are supposed due to the interference of a direct ray over the surface of the earth, and a single reflected ray, passing from the earth to the Heaviside layer and back to the receiver. But the problem is scarcely so simple as this, for the multiple reflection may occur, the ray passing many times between the earth and upper layer before reaching the receiver. Such an effect would obscure the main results if the intensity of these rays were of the same order as those of the direct ray.

About a year ago I made a mathematical investigation of the case, where the bounding surfaces are assumed to be plane; the results obtained are of interest in connexion with the present problem.

Very briefly, the electric force at the receiver due to a current I in a transmitter of effective height (h) situated on the lower of the two surfaces consists of the direct wave:

$$\text{i.e.} \qquad \frac{120\pi hI}{\lambda x}\cos\left(\frac{2\pi}{\lambda}x - pt\right),$$

together with a finite number s of terms of the form

$$\frac{120\pi hI\sqrt{1-\beta_m^2}}{2H\sqrt{\lambda x}}\cdot\cos\left(\frac{2\pi x}{\lambda}\sqrt{1-\beta_m^2} - pt + \frac{\pi}{4}\right),$$

where s is the nearest integer less than $2H/\lambda$, and H is the height of the layer, λ the wave-length of the transmitted wave, x the distance, and

$$\beta_m = \frac{(s-m)\lambda}{2H},$$

m being an integer which varies from zero up to s. These terms represent a series of progressive waves which travel to and fro between the upper and lower surfaces along rays which are inclined at angles θ_m to the earth's surface where $\sin\theta_m = \beta_m$.

Together with these there are a series of stationary wave terms which are unimportant compared with the progressive waves at distances large compared with the height of the Heaviside layer.

The effect of resistance in the bounding layers is to introduce an attenuation factor in each of these terms of the form $E^{-\alpha s/\sqrt{\lambda}}$ and to modify the intensity only to a second order amount.

The state of affairs in the space between the two layers is very complex, especially when a wave-length is used which is very small compared with the height. The object of this letter is to point out the conditions under which the simple theory is applicable, and also to show how these mathematical results may be used to determine the height of the Heaviside layer in the daytime, a determination which is beyond the scope of Prof Appleton's experiment, since the interference effects with which he deals do not occur in the daytime.

With regard to the first question, I agree with Prof. Appleton that there is evidence that the bounding surface of the upper conducting layer is not sharply defined, and that there must be a more or less gradual transition This would favour the reflection at glancing incidence compared with that at normal or nearly normal incidence.

If, then, the receiver were fairly close to the transmitter so that the distance between them were of the same order as H, multiple reflections might not occur, and the results might be explained by the simple theory; but the fact that fading effects as well as directional variations have been observed so close as twenty miles from the transmitter, shows that high angle reflections must not be entirely neglected. Experiments must decide whether they are or are not of importance in Prof. Appleton's case.

With regard to daytime transmission, I think that in spite of the fact that there are no signs of interference phenomena, transmission on long wave-lengths, and as recently shown, on very short wave-lengths, must be effected by the help of an upper layer, which for long waves acts as a pure conductor and for very short waves as a refracting medium with ionic dispersion.

This view is upheld by the results of a large number of measurements made during the past three years, the results of which will be published shortly in a paper before the Institution of Electrical Engineers. These indicate that for transmission on waves longer than

about 5000 metres, diffraction alone is wholly inadequate to account for the signals obtained.

If now we assume the presence of some reflecting or refracting layer, the foregoing mathematical theory can be applied at a distance large compared with H, but small relatively to the earth's radius, so that the curvature can be neglected.

In actual practice the interference between the large number of terms postulated by the theory is not present, and this may be accounted for by assuming that the layer is a good reflector only for glancing incidence, in this case it can be shown that only the zero order term remains (with $m = s$, $\beta_s = 0$),

$$i.e. \qquad \frac{120\pi hI}{2H\sqrt{\lambda x}} E^{-\alpha x/\sqrt{\lambda}}$$

apart from the direct wave, which, varying inversely as the distance, is negligible at greater distances than a few hundred kilometres

Now the experimental results show that the observed signal strength E can be expressed very well by a formula of this type in which the value of H is approximately 40 km This must be regarded as only an equivalent value since the lower surface of the layer is probably very ill-defined. T. L. ECKERSLEY.

Marconi's Wireless Telegraph Co., Ltd.,
Chelmsford, March 20

The Absorption of Cathode Rays in Aluminium.

IN a recent paper in the *Physical Review* (December 1924), H M Terrill gives some measurements of the variation in the fraction of a beam of cathode rays transmitted by an aluminium foil when the velocity of the rays is varied. These results are not in agreement with those published by me (Proc Roy. Soc A, vol. 104, 1923), and the author states that "Whiddington, and later Schonland, worked with rays of uniform velocity produced by magnetic sorting, but the results obtained by them are not in agreement with each other nor with those of the earlier writers. It is believed that the lack of agreement in these results may be traced to the difficulties of velocity determination."

This is scarcely correct. A variety of causes rendered the work of the earlier writers unsatisfactory from a quantitative point of view, while the experiments of Whiddington suffered from an important defect, for no precautions were taken against the disturbing effect of the emission of secondary rays from the foil. My apparatus was designed to remove this source of error, and when allowance is made for the secondary emission, Whiddington's results are in satisfactory agreement with my own.

Dr. Terrill's explanation of the difference between his results and mine would require a correction to my values of $H\rho$ amounting to about 20 per cent., while I am certain that they are not at fault by more than 2 per cent., the measurements having been repeated with a new and differently wound solenoid

That the difference is, however, not due to this cause at all but to the experimental arrangement for measuring the fraction transmitted, is shown by the fact that our results for the velocity of those rays which are just unable to penetrate the foil (the "Range" velocity) are in close agreement. Thus, for a foil 0·00031 cm. thick he finds 19,000 volts, and I, 19,500 volts for the P.D. corresponding to this velocity. This indicates that my velocity measurements are substantially correct and that the differences between our results arise from errors in the measurement of the fraction transmitted.

I believe that Dr. Terrill's arrangement for this purpose is open to criticism, principally owing to the method adopted to prevent the emission of secondary rays from the foil, but also to the fact that so small a fraction (< 1/1000) of the cathode ray beam was employed in the actual measurements. I have had experience of both these causes of error and found them to be very serious.

University of Cape Town,
February 18.

Adsorption of Acids by Purified Silica.

IN the issue of NATURE for January 31, p 157, it has been stated that hydrated silica free from all impurities adsorbs acids The amounts adsorbed by these samples are, however, small. We have since found that if thoroughly washed hydrated silica prepared from pure silicon tetrachloride be allowed to be partially dehydrated in air at room temperature, it shows a marked increase in its capacity to adsorb acids, as the following data will show

Electrolyte.	Concentration	Amount of Adsorption per 10 grams of Hydrated Silica
Oxalic acid	N/2	46 0 c c of N/10 solution
	N/10	7 5 " " "
	N/50	1 0 " " "
Potassium oxalate	N/2	45 0 " " "
	N/10	7 5 " " "
	N/50	1 0 " " "
Sodium oxalate	N/10	7 5 " " "
	N/50	1 0 " " "
Hydrochloric acid	N/2 (F 1 08)	42 0 " " "

The samples are free from all impurities At equivalent concentrations, neutral oxalates and oxalic acid show equal adsorption of the oxalate ion, which, together with the increase in the negative charge of the silica in contact with solutions of neutral salts of low concentrations, proves that we are dealing with anion adsorption as suggested by the writer to account for the latent acidity of sour soils. The large amounts of acids adsorbed leave no doubt that Joseph and Hancock were mistaken in stating that purified silica cannot adsorb acids That they could not observe any adsorption of acids by silica was due to their using ignited silica, as we have found that on ignition the power of silica to adsorb acids greatly diminishes.

In my previous letter referred to above, a mistake occurs (page 158) in the P_H value for the acidity developed on interaction between barium chloride and potassium sulphate. The value given was 2, whereas it should have been 5

Method of Measuring Deep Sea Tides.

IN the course of a conversation with William Beebe regarding plans for work to be done on his oceanic expedition, my attention was directed to the fact that no method had been devised up to the present time for recording the rise and fall of the tides except in comparatively shallow waters. It appeared that the Hydrographic Office was very anxious to have data regarding the tides at localities where the depth of the ocean was measured in miles.

The problem looked rather hopeless at first sight, but on thinking about it, the idea occurred to me that if we could make an artificial island, reaching up from the sea floor to within a few feet of the surface, the rest would be easy. Such an island could be made by means of a submerged buoy

anchored to the sea bottom by a wire. If the ocean were calm, and there were no currents, this buoy would remain in a fixed vertical position above its cement anchor at a constant distance from the ocean floor. If the buoy contained a self-recording barograph of special design operated by the pressure of the water above the buoy, the periodic rise and fall of the tide would be recorded.

Other factors might, and probably would, be present which would cause a variation in the height of the water above the buoy. Ocean currents, by causing the buoy to swing out from the vertical, would depress it, and there would of course be a rapid periodic change due to waves. It seems probable, however, that if the curve drawn on the revolving drum of the barograph was subjected to analysis by passing it through such a machine as Prof. Michelson's harmonic analyser, the tide curve would come out uncontaminated by the variations contributed in other ways.

The scheme could be tried at very small cost. The first experiments should be made in comparatively shallow water (say three or four hundred feet), and the depth gradually increased. For deep sea work the position of the submerged buoy would have to be marked by a smaller surface buoy. The action of the wind on this would introduce another disturbing factor, which would disappear, however, in the analysis of the curve.

Electricity in Curved Space-time.

It is often thought that the theory of curved space-time (general relativity theory) accounts for gravitation but *does not account for the electromagnetic phenomena*. This is not so.

In the general four-dimensional space, the Riemann tensor which characterises the curvature at each point can be shown to be the sum of two parts. We may characterise these two parts geometrically, using Hamilton's device of telling what a thing is by telling what it does. What a Riemann tensor does is to assign to every two-dimensional direction, or orientation, a certain number—its curvature; the first of the two parts mentioned above is characterised by the property that it assigns to two (absolutely) perpendicular orientations *equal* curvatures, while the second part assigns to such orientations *opposite* curvatures. We may mention that of the twenty constants which are needed to give the complete Riemann tensor, the first part involves 11 and the second 9.

In the case of the physical space-time, the first part accounts for gravitational phenomena and the second for electromagnetism, we do not know much about the first part outside the fact that it satisfies the so-called cosmological equations (in fact, to say that a Riemann tensor satisfies the cosmological equations is equivalent to the statement that it only consists of the first part). Our information with respect to the second part is much more complete: if f_{ij} is the electromagnetic tensor and r_{ij} the tensor associated with its reciprocal or dual, the second part can be written as $\frac{1}{2}(f_{ij}f_{kp} - r_{ij}r_{kp})$; conversely, if the second part is given in a region of space-time, this determines the electromagnetic tensor in this region. This result follows easily from an earlier work of the writer (Proc. Nat. Acad. of Sciences, April and July 1924; Trans. Amer. Math. Soc., January 1925).

Artificial Incubation.

In the account of Mr. Llewelyn B. Atkinson's article on "The Scientific Principles of Artificial Incubation" (NATURE, February 21, p. 282), the author is quoted as saying that practically every type of incubator has the air too dry. If this is so, the number of eggs hatched should be dependent to some extent on the humidity of the outside air. That this is the case is we think borne out by the following. We took the percentages of fertile eggs hatched out at Fishponds Poultry Farm, Netley Abbey, and correlated the figures with the relative humidity deduced from the dry and wet bulb readings at Calshot, four and a half miles distant. The hatchings considered were from December 17, 1923, to March 12, 1924, there were hatchings on 26 days; the largest number of eggs hatched out on any one day was 95, the smallest two 37 and 60, the highest percentage of fertile eggs hatched on any one day was 93·2, the lowest 63·5. The readings at Calshot are those taken four times in the twenty-four hours, and we have taken them from the Daily Weather Report. The following values were found for the correlation coefficient between the percentages of hatchings and the mean relative humidity for various periods:

	Day of Hatching.	7 Previous Days.	14 Previous Days	21 Previous Days
Correlation coefficient .	0·31	0·55	0·69	0·68
Standard error .	0·18	0·14	0·10	0·11

It seems, therefore, that the hatchings were dependent to some extent on the mean relative humidity of the outside air during the greater part of the period of incubation.

Solutrean Art.

PROF. SOLLAS, in his letter to NATURE, March 21, p. 420, refers to M. Peyrony's interesting discovery of a carving in high relief in a Solutrean level in the Dordogne. In this connexion it is worth noting that, some months before M. Peyrony's discovery, Dr. Henri Martin had found fragments of limestone bearing engravings of animals in an Upper Solutrean site (still unpublished) in the Charente.

These two finds, so nearly simultaneous, are very important, as Prof. Sollas points out, but it is only fair to recall the fact, apparently overlooked both by M. Peyrony and Dr. Martin, that the credit of being the first to find a work of art in an undoubted Solutrean milieu belongs, not to either of them, but to the Abbés A. and J. Bouyssonie and L. Bardon, who in 1908 found in the Upper Solutrean level of the rock-shelter Pré-Aubert near Brive a slab of sandstone engraved with the rough but unmistakable figure of a horse (*Revue anthropologique*, 1920, p. 188.)

At a moment when discoveries of Solutrean art are exciting great interest both in Great Britain and in France, it is merely just that full credit should be given to the three indefatigable scientists whose work, so little advertised, has been of such fundamental importance to prehistoric archæology.

Mutation.[1]

By Prof. R. RUGGLES GATES.

THE term mutation in the modern sense means a discontinuous germinal change. Conceptions of continuity or discontinuity have played an important rôle in the history of thought not only in biology, but also in other sciences, notably physics and geology. In the latter science the earlier and cruder theories of catastrophism, in which the sudden extinction of floras and faunas was followed by the creation of new ones, were superseded by the uniformitarianism of Lyell. This, coupled with the slow and gradual modification of species as upheld by Darwin, led to a complete triumph of "continuity." But with the followers of Darwin it frequently reached an extreme expression which was not in accordance with the facts of biological variation It was thought that variations which were often spoken of as infinitesimal, could be accumulated in any direction to produce new species. But to produce a new species by this method, such accumulation of infinitesimals must take place simultaneously in several diverse directions, for species differ from each other in a number of independent characters.

Neither Darwin himself nor Wallace ever contemplated infinitesimal variations as a source of new species. Darwin was at pains to show that the gaps between species or varieties could frequently be bridged by intermediate steps, but he was too widely observant of actual variations in plants and animals to make the mistake of assuming complete continuity in all variation. The innumerable cases of variation which he cites in the "Origin" and the "Animals and Plants" usually concern differences which are relatively large compared with many which we now cite and study as discontinuities. The mutations of Drosophila, for example, such as the eye colour series, represent differences which are smaller than anything upon which Darwin relied for the origin of new forms. When all these eye colours are placed together they represent so close a series that to the average naturalist they appear to show complete continuity even under the microscope; and even the expert can scarcely sort all the individuals belonging to the different types in this series with certainty. Yet we know that they arise as marked discontinuities and not as steps in a consecutive series. They are moreover independently inherited, belonging often to quite independent groups of characters

Biological controversy on this subject has oscillated somewhat like a pendulum gradually coming to rest. Each time the upholders of continuity have pointed out an apparently continuous series, their opponents have replied by showing progressively smaller discontinuities within the series. Waagen, Korschinsky, Bateson, W. B. Scott, de Vries, Morgan and others have taken part in this controversy.

Continuity or discontinuity is then a purely relative matter. Series of variations which Darwin and his contemporaries would have regarded as showing complete continuity biologists of this generation have shown by breeding experiments to be inherited as independent units. The essential point is not whether the series appears continuous or not, but whether the differences depend on fixed inherited units. Two series of variations may overlap so as to appear like a single continuous series and yet may depend upon two independent units of inheritance.

When we touch modern physics discontinuity appears everywhere. To the senses matter is continuous, but no scientific man doubts the atomic and molecular, that is, the discontinuous, structure of matter. The atom itself, once regarded as an ultimate unit, is now decomposed into electrons with definite orbits revolving about a nucleus, the analysis of which into protons and electrons has only just begun. Planck's theory of quanta of energy or action extends discontinuity from matter into the field of energetics, and even radiation is now considered as a discontinuous process. Sir Oliver Lodge, in his presidential address to the British Association at Birmingham in 1913, said, "So far from nature not making jumps, it becomes doubtful if she does anything else." Even the ether of space is not retained as a continuum to serve as a background for these physical events. It cannot be adequately used in physical theory except by giving it a granular, that is, a discontinuous structure.

I refer to these similarities in the history of physics and biology, to show that discontinuity is a philosophical necessity in scientific analysis. The mere process of analysis of any structure, however large or small, whether it be a star, a chromosome or an atom, endows it with parts which have relations with each other and are more or less disconnected.

The real problem for the biologist is, then, to determine whether his units in the study of variation are rightly chosen, so that the laws of their inheritance can be followed. In the modern point of view, variations are of two sorts: (1) mutations, which form a new point of departure and are inherited, and (2) fluctuations, which are merely deviations grouped on either side of the mean, produced by environmental or nutritional disturbances and not inherited. This distinction we owe to de Vries, whose "Mutation Theory," first published in 1901, marked, together with the rediscovery of Mendelism, the beginning of a new era in the study of evolution

Before outlining the theory of mutation, in the later development of which my own work has played some part, I wish to refer briefly to a few of the earlier observations and theories of discontinuity in variation. The earliest actual mutation recorded is that of *Chelidonium laciniatum* Miller, a subspecies derived from *C. majus* Linn. the common celandine, a monotypic genus of the poppy family. This laciniate variety was found by an apothecary named Sprenger growing in his herb garden at Heidelberg, about 1590, among typical plants. It was new and unknown to the botanists of his time; it bred true from seeds and has continued to do so ever since. It differs from the type in having laciniate petals and leaves. Such variations are by no means uncommon, the cut-leaved varieties of many trees such as the birch, etc., being of this character.

We need not pause here to consider whether the laciniation first arose at the time when it became

[1] From a lecture delivered at King's College, University of London, for the Board of Studies on the History, Principles and Methods of Science.

externally visible or whether it had been carried germinally as a recessive condition for some previous time. Nor need we probe here the question whether the germinal change involved arose in a pure line or in a line the ancestors of which had been derived from the intercrossing of distinct types within the species Something distinct and new has declared itself, and we call it a mutation, recognising that further analysis will throw much light on the precise manner of its origin, that is, the nature of the germinal change involved.

The conception of discontinuity in evolution did not originate with de Vries, although he was the first to investigate it by experimental methods. Without tracing its sources in biology, its modern emphasis began with Bateson, whose "Materials for the Study of Variation," in 1894, marked a reaction from the morphological problems then current in zoology and from the post-Darwinian attempts to explain evolution entirely through the accumulation of infinitesimal variations by natural selection Bateson's subsequent development of Mendelian theory has been a continuation of views there set forth

Another work which had an important effect, especially on botanical thought, was the "Intracellular Pangenesis" of de Vries, first published in 1889. The views there expressed were themselves derived from the development and modification of Darwin's provisional hypothesis of pangenesis, set forth in the last chapter but one of the "Variation of Animals and Plants under Domestication." This hypothesis of representative particles or gemmules assumed that every cell of the body is represented by particles which multiply by division as the organism develops. These particles (1) not only grow and multiply and are thrown off from the cells, but (2) they "aggregate themselves into buds and the sexual elements," by this means transmitting their qualities to the next generation. The hypothesis of de Vries discarded the second part of Darwin's hypothesis (which Darwin had introduced to account for the assumed inheritance of acquired characters) while limiting the first part, so that pangens were not extruded from the cells but controlled the development of a cell by passing from its nucleus into the surrounding cytoplasm

Both Strasburger in cytology and Pfeffer in plant physiology adopted the term and the conception. The necessity for some such conception to account for the phenomena of development and heredity has been felt by many other physiologists, such as Verworn with his biogens Physiologists who deny the necessity for such a conception have not occupied themselves seriously with the study of heredity. Chromosome division in mitosis must itself be looked upon as an hereditary process—an essential act of reproduction—and the chromosome as a body composed of autogenetic substances which show alternately the phenomena of growth or multiplication and division. The chromosome, as the most conservative body in the cell, thus makes possible the phenomena of heredity. The autogenetic particles which it is assumed to contain tend with increasing knowledge to lose their "representative" character and to become more purely chemical aggregations.

The whole history of the many conceptions of biological units furnishes but another example of the necessity for discontinuity in scientific analysis. The modern gene or factor, which is essential to the explanation of Mendelian heredity and mutation, is the same particle under another guise, the properties and modes of action of which are gradually becoming more precisely defined. Each such gene may have come into existence through the alteration of a previous element, and not necessarily through the loss or gain of a "particle." The philosophical necessity which Darwin himself felt, and which was the *raison d'être* of his hypothesis of pangenesis, has been followed by a long historical chain of representative particles, such as the ids and biophores of Weismann, down to the modern gene, which has been stripped of some of its mystery but is still essential for an explanation of the phenomena of heredity and variation.

In the original work of de Vries with *Oenothera Lamarckiana*, a number of new forms or mutations were described as arising, which usually differed from the parent in a number of features. Later cytological investigations, beginning in 1906, made it clear that the origin of many of these new types was concerned with changes in the number of chromosomes. This finally led to the formulation of the cell theory of mutation,[2] in which it was indicated that Mendelian mutants, such as *Oe brevistylis* and *Oe. rubricalyx*, had arisen as the result of a change in one element or gene of a chromosome, while such mutants as *lata* and *incurvata*, which possessed an extra chromosome, had appeared in connexion with an irregular reduction division of the chromosomes in the parent Since the extra chromosome was found in every cell nucleus, the conclusion was clear that a mutation represented a germinal change which was transmitted by mitosis to every cell. This point of view has been strengthened by many subsequent discoveries A whole series of Oenothera mutations with 15 chromosomes is now known.[3]

The origin of the mutant *Oe. gigas* involved still a different type of germinal change, for in this case the chromosome number was doubled (28). This was the first instance in which tetraploidy was shown to occur under experimental conditions. *Oe. gigas* is so distinct from *Oe. Lamarckiana* in all its characters that if found wild it would undoubtedly be described by systematists as a new species. There is even a conspicuous change in the shape of the pollen grains. Polyploidy, or the multiplication of the chromosome series, is now known to have played a part in the evolution of many plant genera.[4]

Another conception based upon the discoveries with Oenothera is that of parallel mutations. It was shown originally in 1912 that *Oe. biennis* can produce a *lata* mutation having the foliage peculiarities, sterile pollen and 15 chromosomes of the *lata* derived from *Oe. Lamarckiana*, but having the small flowers of its parent *Oe. biennis*. Innumerable cases of such parallel mutations are now known,[5] and the principle is bound to play an important part in the future interpretation of phylogenies.

Many other developments in the theory of mutation have occurred since 1901. The experimental work with Mendelism and mutations has shown that these two fields of research are fundamentally in harmony and can be further developed under a common point of view.

The Manufacture of Blue Water Gas.

THE manufacture of water gas first became an industrial proposition in 1873 with the introduction of the intermittent system by Strong and by Lowe in the United States. Strong, who aimed at manufacturing blue water gas mainly for heating purposes, utilised the heat value of the "blow" gases to superheat the steam admitted to the generator. Lowe, on the other hand, aimed at producing a gas of high illuminating value, and utilised the large quantities of combustible gas produced during the "blow" periods for heating chambers in which enriching oil was decomposed. No real progress in the manufacture of water gas in Great Britain was made until 1888, when a plant was installed at the Leeds Forge Since that time the utilisation of water gas has advanced rapidly, and the manufacture of water gas, both blue and carburetted, is now an important auxiliary in the production of gas for town supply.

The blue water gas process, according to general British practice, may conveniently be divided into two distinct operations. The hot fuel, usually coke, is first raised to a high temperature by the admission of air at such velocity that the pressure below the generator grate is 12 to 18 inches water-gauge This operation, known as the "blow," occupies from one to three minutes. The gases produced are blown away to the atmosphere through the stack, either directly or after combination with air and passage through a waste heat boiler When the temperature of the coke has been raised to the required degree, the air supply is closed, and the bed of fuel is submitted to the action of steam supplied at a measured rate. The steaming operation, which is known as the "run," occupies from four to ten minutes according to the cycle of operations adopted. The blow and run operations are carried out alternately during a period of several hours, at the end of which the operations are suspended for the removal of ash unless mechanical grates are provided.

BLOW PERIOD.—The addition of heat to the bed of fuel during the blow period results mainly from that developed by the oxidation of carbon to carbon monoxide and carbon dioxide, and provided other conditions remained unchanged, the degree of heat addition would be dependent on the proportion in which these two gases are produced. The principal reactions which take place may be represented by the equations:

$$(1)\quad C + O_2 = CO_2 + 97{\cdot}3 \text{ Cal.}$$
$$(2)\quad C + \tfrac{1}{2}O_2 = CO + 29{\cdot}0 \text{ Cal.}$$

The aim during the air-blow should therefore be to obtain the maximum amount of carbon dioxide and the minimum of carbon monoxide. The first reaction predominates at lower temperatures and the second at higher temperatures. The efficiency of heat generation therefore decreases with rise of temperature.

RUN PERIOD.—When steam is passed over incandescent coke, of the reactions which occur, consideration should be given to the following:

$$(3)\quad C + H_2O = CO + H_2 \textit{ minus } 29 \text{ Cal.}$$
$$(4)\quad C + 2H_2O = CO_2 + 2H_2 \textit{ minus } 19 \text{ Cal.}$$

At temperatures above 1000° C., the products of reaction of steam and carbon are almost entirely carbon monoxide and hydrogen. At lower temperatures the importance of reaction (4) increases, and the proportion of steam decomposed decreases.

From consideration of the reactions which take place in the intermittent process of manufacture of water gas, it is clear that in order to obtain high efficiency of heat addition during the air-blow, the fuel must be kept at a comparatively low temperature, and the time of contact of the gases with the hot fuel must be small. On the other hand, to obtain a high efficiency during the steaming operation, the fuel should be kept at a high temperature, and a longer time of contact must be allowed. It is evident, therefore, that these opposing factors must be taken into account in determining the conditions of best efficiency for the whole process.

During recent years, the large scale production of water gas has been the subject of investigations by a Research Committee of the University of Leeds and the Institution of Gas Engineers, and by the Fuel Research Board. From the data procured, thermal balances were constructed. As an example of a thermal balance under conditions typical of British practice, the following is taken from the tenth report of the Research Committee of the Institution of Gas Engineers:

HEAT BALANCES IN THERMS PER 1000 CUB. FT. WATER GAS MADE.

Heat supplied—		
(*a*) Coke to generator		4·900
(*b*) Fuel to raise steam to generator		0·551
(*c*) ,, ,, ,, turbine		0 643
(*d*) Sensible heat of air to blower	Minus	0·001
		6·093
Accounted for as follows—		
1. Water gas, potential heat		2·960
2. ,, ,, sensible heat		0·171
3. Steam not decomposed (total heat)		0·163
4. Blow gas, potential heat		1 042
5. ,, ,, sensible heat		0 462
6. Heat lost in raising steam to generator		0·165
7. ,, ,, ,, ,, turbine		0·193
8. Heat of steam used and lost in turbine and blower		0·446
9. Ashes, potential heat		0·207
10 Clinker ,, ,,		0·017
11. Dust ,, ,,		0·070
12. Ashes, clinker, and dust, sensible heat		0·020
13. Losses, not separately determined, leakages, radiation, convection, etc (difference)		0 177
		6·093

In a paper presented a short time ago to the Institution of Chemical Engineers, Dr. M. W. Travers has studied the results of the investigations previously mentioned Dr. Travers is of the opinion that in addition to thermal balances of the type illustrated, thermal accounts should be constructed to show the amounts of heat added to the fuel during the blow periods and abstracted during the steaming operations. These two amounts of heat should be identical provided that the whole of the necessary data is available with a high

degree of accuracy. The problem, however, is complex, and many other factors in addition to the main carbon-oxygen and carbon-steam reactions must be considered. The coke supplied to the generator invariably contains moisture, hydrogen, sulphur, nitrogen, and ash, and these constituents take part in a number of reactions which cannot be neglected. The amount of water vapour in the air supplied to the generator also has an important effect on the heat account. Separate thermal accounts for the "blow" and "run" periods would undoubtedly be of value, but further study of the subject is required before these can be constructed with sufficient accuracy to enable trustworthy conclusions to be drawn. A. PARKER.

Obituary.

PROF. AXEL WIRÉN.

THE death of Prof Axel Wirén of Upsala has deprived zoology of an able original worker and a distinguished teacher in the University of Upsala. Born on July 12, 1860, in Eskilstuna on the western or landward side of the province of Sodermau Land, about 50 miles west of Stockholm, and the eastern border of which (province) reached the sea, Wirén received his early education at the school of Norrköping, in which his matriculation examination also took place, and he afterwards entered the University of Upsala, where he graduated as Ph.D. in 1885, his thesis being on the circulatory and digestive organs of certain families of polychæts.

From the first the young graduate was attracted to marine zoology and at a time when several departments were sorely in need of scientific advancement. He set himself to work up the zoology of Upsala, especially the chætopods, and by and by he published a series of important researches in the Kongl. Svensk. Vetersk.-Akad. Handl., all finely illustrated by his artistic pencil, the plates varying in number from 5 to 10 (4to) in each communication. The accuracy and beauty of these plates and the value of the accompanying researches would alone have given him a solid reputation. They dealt chiefly with the circulatory and digestive organs of the polychæts, though the minute anatomy of the solenogastres was also worked out with conspicuous ability. Amongst his interesting novelties was the discovery of *Hæmatocleptis terebellidis*, a parasitic eunicid living in the wall of the chitinous stomach of *Terebellides Strœmi*—just as Spengel had found another polychæt, *Oligognathus Bonelliæ*, in the cœlom of Bonellia. Besides other papers he published one on *Nereilepas fucata* in its atokous and its epitokous forms, and the changes in its body-wall, as well as a work on the elements of zoology, a useful treatise for his students. He also gave an account of a visit he made to the museums and zoological institutes of Germany in 1891.

Besides his own strenuous labours in upholding zoology at Upsala—mindful of his responsibilities—Wirén encouraged the young graduates and others to carry on original work in his department, and exerted himself in founding the zoological institute of the University from which many important memoirs were issued. These were published in the series of the "Zoologiska Bidrag från Uppsala" (large 8vo), edited by Prof. Wirén. The perusal of these fine memoirs (the expense of which was partly defrayed by the generosity of the late consul, R. Bünsow) raises a feeling of regret that, in a great country like Britain, zoological institutes on the sea beach should be closed for lack of men, interest, and money, instead of continuing the fascinating researches in marine zoology and botany—not to allude to the importance of these in connexion with the fisheries.

Prof. Wirén was elected to the chair of comparative anatomy at Upsala in 1893, after holding various minor posts. He became professor of zoology and Director of the Zoological Institute in 1908, and held these offices until his death on January 22 last. He worthily served his country and science.

W. C. MCINTOSH.

MR. W. H FINLAY.

A CORRESPONDENT at Cape Town sends us some particulars of the life and work of Mr. William Henry Finlay, formerly chief assistant in the Royal Observatory, Cape Town, who died there on December 7, 1924. Mr. Finlay was born at Liverpool on June 17, 1849, and educated at Liverpool College School. He proceeded to Trinity College, Cambridge, graduating 33rd Wrangler in 1873. In the same year he was appointed first assistant at the Cape Observatory, when Mr. Stone, who succeeded Sir Thomas Maclear, was H.M. Astronomer. Mr. Stone's directorate is chiefly remarkable for the enormous amount of arrear reductions of transit observations which he accomplished, and for his well-known 1880 Cape Catalogue of Stars. In all this work Mr. Finlay took his full share.

As an observer, Mr. Finlay was very zealous in the observation of comets and occultations of stars. He independently discovered the great comet of 1882, and also one, which bears his name, in 1886, and undertook the difficult task of computing its elements as well as of many another. Perhaps in astronomical circles he will be best remembered by his excellent Star Correction Tables, which exemplify the clear grasp he had of his subject, and the orderly practical habit of his mathematical mind.

In addition to his purely astronomical work, Mr. Finlay took an active part in the geodetic work which Sir David Gill, who succeeded Mr. Stone, undertook during his famous directorate. He took the principal share in the longitude operations for connecting Aden with Cape Town, and on his voyages to and from Aden he took advantage of the short stoppages of the steamer at Delagoa Bay, Quilimane, Mozambique, and Zanzibar to determine local time at these places with portable instruments, and to exchange time signals with Cape Town. These observations and the resulting longitudes were published in the Monthly Notices of the Royal Astronomical Society.

In 1887 Mr. Finlay undertook the discussion of the tidal records of Table Bay and Algoa Bay, and the result of his analysis, which is published in the Journal of the South African Philosophical Society, is still the

basis for all tidal predictions at those ports. In addition to these activities, he became the general secretary of the Society from 1881 to 1887, in which year he was elected president. He was also a member of the Cape Meteorological Commission.

When the staff of the Royal Observatory was reorganised in 1897, Mr. Finlay was appointed the chief assistant, but owing to ill-health he was obliged to retire on pension the following year. He spent several years in England, where he completely regained his health, and upon his return to South Africa he took up the work of teaching, a task for which he was eminently suited. When Prof. Williams, of the Rhodes University, Grahamstown, left South Africa to take part in the War, Mr. Finlay took his place as professor of mathematics and surveying, and he remained there at work after Prof. Williams had returned, to within a few days of his death.

LÉON MAQUENNE.

LÉON MAQUENNE, whose death is announced, was born in 1853, and will be remembered as one of those able experimenters and clear-sighted research workers who made notable discoveries in the domain of organic chemistry when the science was still in its infancy and before any really definite views as to the structure of carbon compounds, especially those of natural origin, had been developed. His most noteworthy contributions deal with the structure of the sugar alcohols, important naturally occurring substances which, for many years, resisted the attack of the chemists of his time, and his first achievement in this field was the determination of the constitution of inositol, a compound which occurs widely in both the animal and vegetable kingdoms. He was able to show that this sugar alcohol was hexahydroxycyclohexane, and thus not only established the structure of the first member of an important new series, but also indicated the close relationship which exists between substances produced in the organism and benzene.

Maquenne was also successful in determining the constitution of perseitol, a seven carbon sugar alcohol which occurs in the leaves of *Laurus Persea*, but his most outstanding work in this connexion was probably the isolation of the dextro form of erythritol by the reduction of *l*-threose, a discovery which was shortly afterwards supplemented by the preparation of *d*-erythritol by his pupil Gabriel Bertrand, who isolated it by the action of the "sorbose bacterium" (bacterium xylinum) on natural erythritol. The two enantiomorphs were then united to form the *racemic* modification which was found to be identical with the compound which Griner had synthesised in 1893 from divinyl. The natural form of erythritol is the *meso* modification, but both the *meso* and *racemic* stereoisomers were prepared by Griner in his synthesis.

Of special importance also is the work carried out by Maquenne on starch, which is embodied in a series of papers published during 1904 and 1905. One outcome of this investigation was the discovery, made with Eugene Roux, that crude starch is a mixture of amylose and amylopectine.

During recent years Maquenne turned his attention more particularly to biochemical problems, and he was able to elaborate many important and delicate methods of analysis. His great range of knowledge led him, however, to carry out researches over a wide field, and to him, amongst other things, is due the preparation of pure acetylene from barium carbide, as well as the method of eliminating nitrogen from the air by means of metallic magnesium, which was ultimately used by Rayleigh and Ramsay in the preparation of argon.

ALL who are concerned in the world of shipping and in the electrical industry will learn with regret of the death on March 17, a few hours before his forty-sixth birthday, of Mr. W. W. Bradfield, general manager of the Marconi International Marine Communication Co., Ltd. Practical radio telegraphy, particularly in connexion with shipping, owes much to Mr. Bradfield, whose connexion with the Marconi Company dates from September 3, 1897, when he entered what was then known as the Wireless Telegraph and Signal Company, Ltd As electrical assistant to Senatore Marconi, in the earliest days of commercial wireless, Mr. Bradfield took part in experimental work on Salisbury Plain, and assisted in the erection of the wireless station at the Needles, Isle of Wight. In the year 1899 he installed the first wireless apparatus on British battleships, and a little later took charge of the demonstrations to the United States Government on board the U.S. battleship *Massachusetts*, while in 1901 he undertook similar demonstrations before the French Government, when communication was established between the French Riviera and Corsica. In the same year he supervised the erection of the famous stations at Siasconset (Nantucket Island) and the Nantucket Lightship. From 1902 until 1908 Mr. Bradfield was chief engineer to the Marconi Wireless Telegraph Company of America, and during this time he took part in the first International Radio-Telegraphic Conference, held in Berlin in 1906.

SIR WILLIAM PECK had occupied the post of City Astronomer of Edinburgh, in charge of the Calton Hill Observatory, since 1889, when the erection of the new Royal Observatory on Blackford Hill set the older building, with most of its instruments, at liberty He was of an active and inventive mind, and interested in all mechanical pursuits, besides astronomy. He constructed many of his own instruments. He was, in addition, a popular lecturer of considerable power and attraction, and was the author of a popular "Handbook and Atlas of Astronomy" and other works. The City Observatory was devoted chiefly to showing the heavens to visitors — a service much appreciated by the citizens. For this purpose a six-inch photovisual telescope, presented to the observatory, was of good service. In pursuance of the science, Sir William Peck visited Spain for the eclipse of 1905, and Egypt in 1908. He received the honour of knighthood in 1917. He died on March 7, after a long illness, aged sixty-three years.

WE regret to announce the following deaths:

Prof. A. Dendy, F.R.S., professor of zoology in the University of London (King's College), on March 24, aged fifty-nine.

Mr. H. E. Jones, president in 1917 of the Institution of Civil Engineers, on March 24, aged eighty-two.

Current Topics and Events.

IT has been common knowledge for some time in the scientific world that the Royal Society intended to dispose of part of the collection of early printed books in its library, especial attention having been directed to the fact in the report of Council issued to fellows in November last, and published in the Year Book of the Society. While it is true that during the last few years the Society has received large gifts of money, it has to be borne in mind that without exception the application of such moneys has been limited to certain definite objects, and none is available for the general purposes of the Society, however badly it may be needed, that, no doubt, explains the last sentence of the president's letter to the *Times* of March 27, "As circumstances stand, sentiment must be tempered by practical expediency." The larger portion of the books are relics of the collection presented to the Society in 1666 by Henry Howard, afterwards Duke of Norfolk, and only those volumes which have no scientific interest or are duplicates are being offered for sale, but two of the books which are likely to fetch very high prices—a Bible, and Richard Baxter's "A Call to the Unconverted," both translated into the Massachusetts Indian language—were presented to the Society in 1669 by John Winthrop, Governor of Connecticut. One of the features of the collection is a series of several hundred Reformation Tracts printed in Germany, more than one hundred of these being by Martin Luther. Among other books of interest are Caxton's second edition of "The Canterbury Tales," 1484, Fust's "Liber Sextus Decretalium" (1465), and Cicero's "De Officiis" (1466). A first edition of Euclid, included in the sale, is a duplicate. It is the intention of the president and Council that the proceeds shall be kept as a separate fund, known as "The Arundel Library Fund," to be used for the purchase of scientific books. A nucleus has already been formed by the sale to the British Museum, at its own valuation, of some seventy items.

THE Council of the Institution of Electrical Engineers has addressed a letter to the Postmaster-General stating that some of the provisions of the Wireless Signalling Bill are of such far-reaching importance that unless they are modified they will prove a serious hindrance to electrical and physical research. In particular the Council desires that it should be made perfectly clear that the words "any apparatus for wireless telegraphy" apply only to such apparatus when used for signalling purposes. Crystal detectors and radio valves, for example, are used in many physical laboratories for testing apparatus and materials which have no connexion with radio signalling. It should be clearly stated in the Bill that licences are not required in these cases. It is also recommended that all regulations made by the Postmaster-General under Clause 3 (Regulations and Fines) of the Bill should be submitted to a statutory advisory committee for consideration, and it is suggested that the committee should be representative of the Royal Society, the Institution of Electrical Engineers, the Radio and other interested societies. We think that this suggestion is a good one and would form an effective barrier against legislation which might injuriously affect research. It is also pointed out that Clause 7 of the Bill, which applies its provisions to the use of etheric waves for the transmission of energy, may greatly interfere with research and industrial development. A new clause might be substituted for it rendering liable to penalties any one using electromagnetic radiations of the frequencies commonly employed in radio telegraphy in such a way as to affect injuriously the working of authorised radio telegraphic stations. It is conceivable that in the future important industries may be founded on the transmission of energy by etheric radiations. Several suggestions for utilising these radiations have already been made, and it would not be in the national interest to hamper unnecessarily research in these directions.

THERE has been a considerable addition to our knowledge of scarlet fever during the last year through the researches of G. F. Dick and his wife, Gladys H. Dick, of the John McCormick Institute for Infectious Diseases in Chicago. Hitherto the causation of scarlet fever, like the other exanthemata, has been completely obscure. It was not regarded as likely that any of these fevers were due to ordinary bacteria, for although bacteria have been constantly found in one and all of them, no single bacterium isolated has been able to reproduce the disease in man or animals. The Dicks have, however, obtained (1923) a streptococcus from a case of purulent infection of the hand of a nurse suffering from scarlatina, and have directed attention to certain of its peculiarities. The application of pure cultures of this streptococcus has been alleged to produce scarlet fever in man, and it is concluded that, after all, scarlet fever is probably a bacterial disease analogous to diphtheria in its general pathogenesis. The organism is supposed to produce a local lesion in the throat, and a soluble poison produced in this site is absorbed into the system and is the cause of the rash and some other manifestations of the fever. By applying the toxin of the streptococcus scarlatinæ to the skin, a very definite red area appears in some persons but not in others. Where this "Dick reaction" is positive the individual is presumed to be susceptible to scarlet fever. Where the reaction is negative the individual is immune. These reactions are strictly analogous to the Schick reactions in diphtheria. It is possible to pick out the immunes from the non-immunes, and by inoculating the latter it is hoped that scarlet fever can be completely controlled as diphtheria has been. These results of the Dicks have been confirmed in all important respects by trustworthy workers in the United States, and the subject is now receiving close attention in Great Britain.

A STEP towards the improvement of loan facilities between libraries of university rank in Great Britain has been taken by the Association of University

Teachers, which recently convened a Conference to consider the matter. As a result, regulations for inter-library loans have been approved, and inquiries are now being dealt with by Mr. Oldaker, the University, Edmund Street, Birmingham, to whom all correspondence should be addressed. The movement is a healthy one, for it represents a reaction against the policy of library inflation which was characteristic of library administration in the latter half of last century. It is now seen that the future needs of the research student can only be met by a pooling of the resources of our research institutions. We have, however, some doubt as to the wisdom of instituting at this stage the inquiry office in Birmingham To provide prompt and accurate answers to inquiries as to the place of deposit of a given work presupposes the existence of an extensive collection of bibliographical serials and library catalogues which are to be found in few municipal or university centres. Moreover, the inquiry officer should have access to the work for the loan of which application is made. Further, the institution to which he is attached should be equipped with modern photographic copying apparatus Few institutions comply with these requirements The A U T. appears to have overlooked the fact that the bibliographical aspects of the problem should in the first instance have been left to the decision of bibliographers. We think it would be wise even at this stage for the A U T to refer its proposals to a small committee of experts to consider whether the institution of a separate inquiry office is best calculated to secure the professed objects, and in case of an unfavourable answer, to authorise the committee to submit alternative proposals.

SIR OLIVER LODGE's seventh and last "talk" of the series on "Ether and Reality," which is being broadcasted from the London station 2LO of the British Broadcasting Company, was given on March 31, and dealt with the probable utilisation of the ether. The ether or continuum has perfect properties, while matter is liable to deterioration and dissipates energy. No law of dissipation applies to the ether; matter exists not only inorganically but also as the complex molecules of protoplasm, which can be animated and made a vehicle for "life." But the coherence of all bodies is effected by the etheric connecting medium, and the question arises: Can that ether body be animated too? We usually ignore the ether body because it is outside the ken of our senses, but knowing what we know of matter and its fields of force, it is reasonable to suppose that we act more directly on ether than on the discontinuous particles of matter. All force is exerted through the ether, and it is thus that matter has become indirectly and apparently amenable to life and mind and memory and affection. These psychic attributes belong to the unseen universe; and if they require a physical medium, the ether is permanently available. Our material bodies have thus been built up, and are worked for temporary purposes of demonstration here and now, but they are imperfect and wear out. Mind may always need a vehicle, a body, a habitation, an instrument, but it need not be made of matter It is doubtful if matter is ever really animated directly. Our present connexion with matter is probably indirect as well as temporary Sir Oliver stated that, in his opinion, permanent reality lies in a region which does not appeal to the senses,—a region of inference, and to that region we really belong.

SIR ERNEST RUTHERFORD, in his discourse at the Royal Institution on Friday, March 27, on atomic nuclei, stated that the most direct method for determining the nature and magnitude of the forces that hold the atom in equilibrium, and the size and constitution of the nucleus, is to examine the scattering of swift α particles when they traverse matter Such experiments have shown that the inverse square law appears to hold over the greater part of the space occupied by the atomic structure. It breaks down, however, when the α particle approaches very close to a light nucleus like that of hydrogen or aluminium. By studying the variation of the number of α particles of different initial velocity scattered nearly backwards from the bombarded material, it has been found that there is a sudden change in the law of scattering for aluminium for a definite velocity Experiments made with thin films of gold and uranium show that the law of the inverse square holds to the closest distance of approach of the α particle to the nucleus, namely, about 3×10^{-12} cm. This is remarkable, for from radioactive information it is believed that the nuclear structure of uranium extends to more than twice this distance A distribution of charged electric doublets in the form of satellites extending some distance from the central nucleus may account for these effects. Previous work has shown that a change in nuclear structure can be brought about by intense collisions between α particles and light nuclei, but the fate of the α particle after liberating a proton has been a matter of great uncertainty Some recent experiments by Blackett show that in the case of nitrogen the α particle may be captured by the nucleus Thus in the case of nitrogen there is on the whole a building up rather than a disintegration. This result is of great importance and interest, but we are still far from understanding the mechanism of such disintegrating collisions.

A SERIES of interesting demonstrations has been given at Messrs Selfridge and Co., Ltd., London, W.1., by Mr. J. L. Baird, of an experimental apparatus of his own design for wireless "television" (*i.e.* the simultaneous reproduction at a distance of an image of a fixed or moving object) The inventor does not claim any great perfection for his results, but we have seen the production in the receiver of a recognisable, if rather blurred, image of simple forms, such as letters painted in white on a black card, held up before the transmitter. Mr Baird has overcome many practical difficulties, but we are afraid that there are many more to be surmounted before ideal television is accomplished. In the transmitting apparatus, the object, strongly illuminated, is placed opposite a revolving disc provided with a series of lenses, each a little nearer to the centre than the last, which project a

series of moving images upon a selenium or other photo-electric cell, each a little displaced laterally from the last. This is the equivalent of passing the cell over the whole surface of the object in a succession of close parallel lines. The light thus reaching the photo-electric cell is rhythmically interrupted by a rapidly revolving slotted disc, and the result is that owing to the variations of resistance of the cell, undulations at an audio-frequency are produced in the current through it, whenever a bright part of the object is being dealt with. These are amplified and supplied to a simple wireless transmitter which is caused to emit corresponding signals.

In the receiving section of Mr. Baird's television apparatus, the signals sent out from the transmitter are detected and amplified by very powerful valves until they are strong enough to light up a neon tube when a signal is received, *i.e.* when a bright part of the object is being dealt with by the transmitting apparatus. A disc with lenses or holes corresponding to the lenses of the transmitting disc is rotated synchronously with the transmitting disc, causing spots of light produced by the neon tube to appear upon a screen in positions corresponding to the part of the object being dealt with. With a sufficiently rapid rotation of the discs, a recognisable image of the object is produced. A duplicate of the receiving apparatus is provided at the sending end with its disc mounted on the same shaft as the transmitting disc, to enable the necessary adjustments to be made. Synchronism between the sending and receiving discs is obtained by a little alternator with a frequency of about 300 geared to the revolving system, which causes signals to be sent out by another wireless transmitter at this frequency. These are received and amplified at the receiving station to an extent enabling a similar little alternator connected to the receiving discs to be synchronised with them.

Dr. A. W. Crossley, presiding at the annual dinner of the Chemical Society on March 26, referred to the difficult position in which the Society finds itself on account of the increased cost of publication. Subscriptions of fellows have been raised, various limitations have been placed upon the distribution of the Society's publications, and papers are curtailed as much as possible, yet there is a financial deficit, and no practical means of avoiding it have yet been found. During the War, chemists saved the nation from disaster by supplying drugs, poison gases and protection from them, and other products demanded by the times, and it does not seem too much to ask that assistance should now be afforded in placing upon record the work they are doing for the advancement of knowledge. When one remembers the vast sums expended upon the verbatim reports of proceedings in Parliament published in the large volumes of Hansard, and considers how trivial most of the matters are in comparison with the original contributions made to a body like the Chemical Society, it is difficult to understand the national sense of value which leaves the Society in its present anxious position. Possibly the additional 1500*l.* received by the Royal Society in aid of scientific publication will enable a grant to be made to the Chemical Society, but in our opinion a very strong case can be made out by many other scientific societies for assistance towards costs of publication, either from the State or private benefactions, and we should like to see a concerted effort made with the view of securing adequate funds for this purpose.

Mr. W. J. U. Woolcock referred at the annual dinner of the Chemical Society on March 26 to a scheme for the establishment in London of a "Chemistry House" which would provide office accommodation for the chief chemical societies as well as one or more lecture theatres and other facilities. The scheme is being put on a business footing, and there is every reason to believe that it will take definite shape before long. It is possible that other scientific societies may like to be housed in the same building, and the plans may be enlarged to enable this to be done if there is a clear demand for such increased accommodation.

So far most of the clinical reports on "Bayer 205," now renamed "Germanin," have encouraged the belief that at last a specific for the treatment of trypanosomiasis has been found. A paper by Dr. Clement Chesterman in the Transactions of the Royal Society of Tropical Medicine and Hygiene (1924, vol. 18, p. 311) is somewhat disturbing from that point of view. Seventeen cases, all well advanced in the "second" or nervous stage of the disease, were treated with the new drug. Of these, nine had already received arsenical drugs without permanent improvement, and eight had not been given any previous treatment. Nine of these cases relapsed in from six weeks to fifteen months after a course of "Bayer 205." Two died of acute nephritis after their discharge from hospital and two from intercurrent bilharzial dysentery. Two more, who had suffered from amblyopia during arsenical treatment, became blind after administration of "Bayer 205," and a third developed amblyopia more quickly than usual when given arsenical treatment after a course of the new drug, due, it is suggested, to the possibility that damage to the kidneys by "Bayer 205" prevented the usual rapid elimination of the arsenic afterwards given. Two cases were definitely improved and have remained so for four and five months respectively. Unfortunately, none of the cases could be re-treated owing to the small supply of the drug available. It is pointed out that the two cases who died from acute nephritis might have been saved by careful nursing but were brought back to hospital too late. Dr. Chesterman has not lost faith completely in "Bayer 205," but thinks it important that "the limitations of yet one more of tropical medicine's 'conquering heroes' should be realised."

The genesis of "Bayer 205" is described in a recent paper (*Zeitschrift für angewandte Chemie*, 1924, vol. 37, p. 585) by Dr. B. Heymann, one of the chemists who took part in the long and arduous researches which resulted in its discovery. There

is a good deal of special pleading for the Bayer Co.'s refusal to disclose the constitution of the new drug, and this is critically commented on by M. Fourneau (who, it will be remembered, re-discovered "Bayer 205," or at least made an effective substitute for it) in *Chimie et Industrie*, 1925, vol. 13, p. 284. Whatever the ultimate value of "Bayer 205" as a remedy for sleeping sickness may prove to be, there can be no doubt that its advent has provided chemists and pharmacologists with new ideas for chemotherapeutical work.

PROF. H. A. LORENTZ, of Leyden, Holland, will deliver the fifteenth annual May lecture of the Institute of Metals on May 6 The subject of the lecture will be "The Motion of Electricity in Metals."

THE seventy-fifth anniversary of the foundation of the Royal Meteorological Society will be celebrated on April 21 and 22. The celebrations include a visit to Kew Observatory and a lecture by Prof. E van Everdingen, director of the Royal Netherlands Meteorological Institute, and president of the International Meteorological Committee

THE Fondation George Montefiore, given every three years for the best original work of the preceding three years on the scientific advance and on the technical applications of electricity, is to be awarded this year The 1923 award was deferred and the prize now amounts to 22,500 francs. The committee of award consists of ten electrical engineers, five of whom are Belgian, under the chairmanship of the Director of the Montefiore Electrical Institute of Liège. Competing works, addressed to M. le Secrétaire-archiviste de la Fondation George Montefiore, Association des Ingénieurs électriciens sortis de l'Institut électrotechnique Montefiore, rue Saint-Gilles, 31, Liège, must be received by April 30 next.

THE first annual report has been issued of the Ella Sachs Plotz Foundation for the Advancement of Scientific Investigation. Thirty-two applications for grants were received from various countries and eight awards were made, involving a sum of 8550 dollars. For the present, problems in or bearing on medicine are to be favoured and preference will be given to groups of researches on a single problem. Thus last year, four of the grants were for work bearing on chronic nephritis. Two only of last year's awards, to Dr. A. Bezredka, Pasteur Institute, Paris, and to Dr. J. Aberlin, Berne, went outside the United States. Applications for grants for 1925-26 must reach Dr. F. W. Peabody, Boston City Hospital, Boston, Mass., before May 15 next.

ARRANGEMENTS are in progress for a meeting of the Commission for the Exploration of the Upper Air to be held at the Meteorological Office, South Kensington, on April 16-22, under the presidency of Sir Napier Shaw. The Commission is in connexion with the International Meteorological Committee. The principal business of the coming meeting is to discuss the publication of the results obtained by balloons and kites in the various countries of the world during the years 1923 and 1924. A sum to meet the expenses of a specimen volume was allocated by the Union of Geodesy and Geophysics at Madrid in October last

AMONG the financial items recently adopted by the French Chamber of Deputies is one of unusual interest to scientific workers. The clause in question is due, according to the *Revue générale des Sciences*, to Prof. Emile Borel, and provides for a tax of 5 centimes on each 100 francs paid in salaries by French commerce and industry, and the products of the tax, which it is estimated will bring in about fourteen million francs a year, is to be allocated to French scientific laboratories. In this way it would seem that industry might be made to contribute directly to the support of the fundamental scientific research on which it is based The measure has still to be passed by the Senate before becoming law

THE Norwich Castle Museum Committee of the City Corporation has under consideration the celebration of the centenary of the foundation of the Museum under the presidency of the famous Norwich botanist, Sir James Edward Smith, F R S, in 1825 The history of the Museum shows that its fortunes were of a varying character until 1894, when the Corporation took over the collections of the Museum Society and housed them in the spacious galleries adjacent to the Castle. The year 1925 is important for the City of Norwich, as in addition to the celebration of the centenary of the Museum, there will be an official opening of the Bridewell Museum of Local Industries in the 13th-century house of the first Mayor of Norwich, which will provide about 11,000 feet of floor space for the exhibition of material illustrative of the textile and other past and present industries of the City of Norwich

IN publishing the first biological number of the Science Reports of the Tohoku Imperial University, Sendai, Japan, Prof. S. Hatai announces the formal opening of the Biological Institute of this University and of a Marine Biological Station, located at Asamushi. Among the special features of this station is an under-sea laboratory and a spacious open marine pool for observations on the growth of marine organisms Several residences and a large dormitory have been erected where investigators may live with their families and where students may find suitable accommodation. Prof. Hatai hopes that his colleagues in Japan and in other countries may take advantage of the facilities offered for research

YEAR-BOOK No. 23 of the Carnegie Institution of Washington, recently issued, contains a report by the Department of Genetics The investigations reported upon range from chromosome studies in Datura and Drosophila, sex conditions in Cladocera, pigeons, and moulds, to the genetics of rabbits, mice, and horses, and eugenic studies of Indian-negro-white racial complexes in Virginia, inheritance of exceptional intelligence, the endocrines of mongoloid idiots, and a European study of the ancestry of American immigrants No attempt can be made here even to outline the results obtained in these and other fields of research, but it is clear that substantial

progress is being made in such problems as the further analysis of the relations between chromosomes and heredity, and the compilation of data on which the improvement (germinally) of the human race could be based.

WE have received the annual report for 1924 of the Crichton Royal Institution, Dumfries—a hospital for mental diseases Both private and rate-aided patients are admitted, numbering approximately 630 and 339 respectively during the year. Some 70 per cent. of the private admissions were voluntary, but all the rate-aided admissions were under certificate, and the medical superintendent, Dr. Easterbrook, comments forcibly on the obsolescent provisions and objectionable terminology under existing statutes which officially distinguish the latter class as "pauper lunatics," and he points out that the absence of definite statutory provision for the treatment of rate-aided patients as voluntaries has had unfortunate results. A well-equipped clinical and pathological laboratory conducts much useful work at the Institution, which has received commendation from the Commissioners of the General Board of Control after inspection.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned Grade IV. of the Civilian Educational Staff of the Royal Air Force, preferably with engineering qualifications and experience.—The Secretary, Air Ministry, Adastral House, Kingsway, W.C.2, Bio-chemist at Dove Marine Laboratory, Cullercoats.—The Registrar, Armstrong College, Newcastle-upon-Tyne, an assistant lecturer in the department of physiology of the Welsh National School of Medicine.—The Secretary, University College, Cardiff (April 11); a lecturer in morbid anatomy and histology in the University of Manchester —The Internal Registrar (April 15), a research fellowship at Somerville College, Oxford, open to Oxford women graduates —Miss Lorimer, at the College (April 16); woman as principal administrative officer of King's College for Women, Household and Social Science Department, Campden Hill Road, W 8 —The Chairman of the Executive Committee (April 16), two assistant lectureships in physics in the University of Manchester —The Internal Registrar (April 18), the professorship of bio-chemistry at Middlesex Hospital Medical School —The Academic Registrar, University of London, South Kensington, S W 7 (April 23), the professorship of chemistry and directorship of the department of chemistry, the University of Birmingham —The Secretary (May 1); four scientific assistants for the science exhibition of the Royal Society at the British Empire Exhibition.—The Secretary, British Empire Exhibition Committee, Royal Society, Burlington House, W 1

Our Astronomical Column.

TWO NEW COMETS.—Comet 1925 *a* was discovered by Herr Schain at Sineis Observatory, Crimea, on March 23. It is of the tenth magnitude and visible in moderate telescopes When discovered it was near β Virginis, and was moving slowly to the north-west Being nearly opposite to the sun, it is observable for most of the night. The following positions have come to hand

G M T (new)	App R A.	App N. Decl.	Observer	Place
d. h m	h m s.	° ′ ″		
Mar. 23 22 43 6	11 47 48·9	1 43 49	Schorr	Bergedorf
,, 25. 23 42 3	11 44 8 3	1 53 46	Vinterhausen	Copenhagen
,, 27 23 37 5	11 40 32 2	2 3 22	Steavenson	Norwood
,, 29 0 22 0	11 38 39 7	2 7 53	,,	,,

The last place depends on an approximate position of the star $BD + 2°$ 2468, mag 9·5, assumed place for 1925·0, $11^h\ 39^m\ 6{\cdot}3^s$, 2° 12′ 12″ Use should not be made of this position until a better star-place is available The comet's R A is diminishing by about $1^m\ 53^s$ daily, its declination increasing by 5′ daily.

The orbit has not yet been calculated, but the ascending node is evidently near 0°, and the inclination not large, this fact would make an elliptical orbit not unexpected

Comet 1925 *b* was found by Mr William Reid at Cape Town on March 24 It should be stated, in correction of some paragraphs in the press, that Mr. Reid, whose diligence and success in comet-sweeping are well known, is not on the staff of the Cape Observatory, but is an amateur

This comet is brighter than the other, being of magnitude 8, but its low altitude is a hindrance to easy observation in England. The following positions have come to hand

G.M T (new)	App R.A	App. S Decl.	Observer.	Place.
d. h m	h m s.	° ′ ″		
Mar. 24. 21 33 0	13 29 47	20 16 0	Reid	Cape Town.
,, 28. 1 9 4	13 26 58 3	21 5 16	Steavenson	Norwood.
,, 28 2 49 0	13 26 54 5	21 6 13		Algiers
,, 29 1 12 0	13 26 0 1	21 20 36	Steavenson	Norwood.
,, 29 1 29·0	13 25 59·8	21 20 54	,,	,,

The R A is diminishing by 54 sec daily, the south declination increasing by nearly 16′ daily

The orbit has not yet been calculated, but, as in the case of Comet 1925 *a*, the observations given should be sufficient to deduce preliminary orbits. Reid's comet is not far from γ Hydræ, and is due south about three-quarters of an hour after midnight. There will be more chance of observing the comets after the moon has set.

BROADENING STELLAR SPECTRA.—In Mon Not. R A.S, vol. 85, p 47, Dr W. J. S Lockyer, Director of the Norman Lockyer Observatory at Sidmouth, describes a new method of broadening stellar spectra for purposes of reproduction. Since stellar images are merely points, the spectra have no breadth unless special methods are adopted to broaden them. For practical purposes it is customary to allow the image of the star to "trail" on the photographic plate by a suitable adjustment of the rate of the driving clock, but very little breadth is usually possible owing to the increased time of exposure entailed. Further, various unavoidable irregularities in brightness make the spectra broadened in this way unsuitable for picturesque reproduction. In the arrangement devised by Dr. Lockyer, the original negative, showing a narrow spectrum (after being specially prepared in a manner explained in the paper) is allowed to fall under gravity in a direction parallel to the spectrum lines, its speed being regulated by a flow of oil which, by an ingenious arrangement, is produced by the fall. During the fall the negative is illuminated by a constant source of light and photographed, the breadth of the spectrum thus obtained clearly being determined by the distance of descent. The paper contains an account of investigations made to determine the most satisfactory time of exposure, and also a beautiful photograph of the spectrum of *a* Cygni broadened by the new method.

Research Items.

THE STONE AGE IN THE EASTERN SAHARA.—In the course of an account of the oasis of Kawar (Kaouar), Eastern Sahara, in *La Nature* for March 14, Capt. Marius Prevost, who writes in collaboration with Dr. Lucien Mayet, describes stone implements found on a considerable number of sites in the oasis explored by him. The implements occur in such numbers as to suggest that the oasis supported a considerable population from an early date In addition to flint, which was imported, quartz, quartzites, silicious limestone, hæmatite and volcanic rocks were used in the manufacture of the implements In the absence of stratification, the only indication of date is the somewhat uncertain evidence of type On this basis certain implements worked sometimes on one side, sometimes on both; flakes, points, carinated implements, etc , would, if found in Europe, be classified beyond question as palæolithic, while others, arrowheads, with or without tang, or triangular, spear-headed knives, polished axes, etc , would belong to the neolithic. Beads and pendants of stone and ostrich shell were also found. The neolithic industry shows strong affinities with that of Egypt which, if contemporary, would indicate an antiquity of 9000 to 12,000 years, and the palæolithic type might therefore be assumed to be older still. Up to the present, neolithic typology in the Sahara seems to point to a great uniformity of culture in the whole area.

ARCHÆOLOGICAL RESEARCH IN CENTRAL AMERICA IN 1924.—A report by Dr. Sylvanus G. Morley, in Year Book No. 23 of the Carnegie Institution of Washington, covers a number of investigations in Central America. A fourth Initial Series from the Maya New Empire region of Yucatan has been discovered. Excavations by Mr. E. H Morris at Chichen Itza in the "Court of the Thousand Columns" have cleared the North-eastern Colonnade, an edifice 100 feet in length by 49 feet in width facing south. On three sides and part of the fourth it was bounded by solid walls, but the remainder of the support of the superstructure was a series of 5 rows of columns, rectangular in cross section. Their height was 8 feet. The season's excavations confirmed the type of the most prevalent form of column-supported structure at Chichen Itza, with a rectangular plan, arches paralleling the longer dimension, and an altar or throne at the centre in the rear. In the course of a survey of the archæological area by Mr. Kilmartin, a number of partly finished sculptures were discovered which throw light on the technical practices of the Maya in this art. Measurements of the great terrace show that it contained an area of 47 acres and, in some places, was built up to a height of 25 feet. At Uaxactun, Guatemala, a structure was discovered which appears to have been a sun observatory. Dates on three stelæ discovered nearby equate with A.D. 97 and A.D. 235, and the observatory, therefore, if it be one, cannot have been erected later than the latter year and was planned before the two earlier stelæ were set up. Excavations by Mr. O. G. Ricketson, jun., in mounds at Baking Pot, British Honduras, have brought to light a number of skeletal remains. In a sepulchral structure were found seven skeletons. In two the upper front teeth were filed, and in one the five upper teeth were inlaid with circular fillings of iron pyrites. All showed signs of fronto-occipital flattening.

FISH TRAPS IN EASTERN ASIA.—The distribution of thorn-lined traps in Assam and farther east is discussed by Mr. Henry Balfour in *Man* for March. The principal feature of these traps is that the inside of a conical trap is lined with the thorns which beset the leaf-ribs of climbing palms (Calamus, Dæmonorops, etc.), the sharp points being set toward the apex of the cone, thus rendering exit impossible when the trap has once been entered. Such traps had not been recorded from the Naga Hills of Eastern Assam prior to 1922, although their existence seemed probable from the Indonesian affinities of Naga culture Inquiry, at first unsuccessful, finally produced an example from the Lhota Nagas from Okotso Village which is practically identical with the forms which range through the Malayan and Indonesian areas and extend as far as Melanesia. Several varieties of similar traps have since been collected from other Naga tribes by Mr J P Mills. Varieties of the trap are noted from Western Burma, Malaya, Sumatra, the Philippines, Borneo, New Guinea, where it is widely distributed, New Britain, and the Solomon Islands. Though the place of origin is uncertain, there is no doubt that these thorn traps are referable to a common prototype and form a connected series.

THE DISCOVERY OF THE ANTARCTIC CONTINENT.—It has long been the practice to credit Sir J. C. Ross with the discovery of the Antarctic continent when he sighted South Victoria Land in 1841 Some years ago the late Dr. W S. Bruce showed that the real discovery was made in 1820, when E. Bransfield sighted Trinity Land, a part of that section of Antarctica now known as Graham Land. In the *Geographical Journal* for March, Lieut.-Commdr R T. Gould publishes the full evidence on which Dr. Bruce based his contention. Bransfield's own log-book has disappeared, but contemporary accounts of his voyage are available. One of these that had previously been overlooked, together with Bransfield's own charts, which are in the possession of the Admiralty, make it clear that in January 1820 he sighted the northern extremity of the mainland in the vicinity of the mountain which now bears his name. Lieut.-Commdr. Gould's article is accompanied by a chart on which Bransfield's discoveries are shown in relation to more modern surveys, and his track is marked as accurately as is possible in the absence of the log of the *Williams*

USE OF STIBAMINE IN KALA AZAR.—In the *Indian Medical Gazette* for January 25, Dr. Napier, who is in charge of kala-azar investigations at the Calcutta School of Tropical Medicine, has an interesting note on the treatment of this disease by derivatives of stibamine (*p*-aminophenylstibinic acid). It is well known that sodium antimonyl tartrate is an effective remedy, but it is slow and the coolie victims prefer as a rule to put up with the disease rather than submit to injections of this drug for several months. Improved remedies are therefore urgently required, and chemotherapeutical and clinical experiments carried on in Germany, England, and India during the last ten years have shown that stibamine is almost certainly as specific in its action in kala-azar as any drug can be. Unfortunately it is unstable and too toxic for use, and the difficulty has been to find a stable form in which to administer it. The acetyl derivative, which at first seemed promising, had to be abandoned after several accidents with it, but three other promising compounds are now under trial; urea-stibamine, which appears to be a combination of carbamide and stibamine of unknown constitution, discovered by Dr. Brahmachari of Calcutta; *meta*chlorostibacetin, produced by von Heyden

of Dresden, and stibamine glucoside, first made a few months ago in the Wellcome Chemical Research Laboratories, which is the subject of the note by Dr Napier referred to above All three new drugs seem to be about equally valuable as curative agents, and the period of treatment by them is reduced to two or three weeks. It is too soon to say which of them will prove most effective, but their advent marks an important step in the treatment of another tropical disease.

THE ŒSTROUS CYCLE IN CATTLE.—H. S Murphey has published a paper on the œstrous cycle in the cow, in the Journal of the American Veterinary Medical Association (vol 65, August 1924), and G W McNutt in the same number has given an account of the corpus luteum in the cow in relation to the cycle. The cycle is divided by the former author into two main periods, diœstrum and œstrum, and the latter is subdivided into proœstrum, œstrum in the restricted sense (*i e* the actual time when coitus may occur), and postœstrum Both the vagina and the uterus are shown to undergo marked cyclical changes, pronounced congestion and œdema beginning with the proœstrum and not subsiding until four or five days later. In the case of the vagina the congestion and œdema are followed by active secretion McNutt describes ovulation as occurring shortly after "heat," an observation which agrees with what has been found by John Hammond, whose investigations at Cambridge have covered much the same ground, but have not so far been published The corpus luteum is said to be formed both from the follicular epithelium and from the theca interna. It may commence involutionary changes after 14 to 16 days, but there is some individual variation. In young animals the involution is completed in a year or somewhat less, but as the cow grows older, involution takes place more slowly and is less complete. The colour of the corpus luteum is at first a light brown, about the 7th day an old gold, by the 14th day a bright golden yellow, and by the 20th an orange colour, eventually changing to a bright brick red The colour change is associated with the quantity and character of the lipoid in the luteal cells.

FRUIT TEMPERATURES IN CALIFORNIA.—A discussion of considerable value to fruit-growers is given in the recently issued *Monthly Weather Review* for August 1924 in an article on "Substitution of fruit temperatures for air temperatures in regulating orchard-heating for oranges" The essential features of the discussion aim at improvement in eliciting a more precise estimate of the lowest temperature to which fruit can be subjected without damage For thirty years or more, orchard-heating has been practised in the United States, mostly without exact data as to effective damage, and based on the reading of sheltered and unsheltered thermometers in varying degrees of proximity to the fruit. The frosts are found not only to render the fruit unmarketable, but also in many cases to prevent the crop being included in the "choice" or "extra choice" grades. Information is given to show how successfully under ordinary cold the fruit escapes damage. A special mercurial thermometer is used; the bulb of the instrument is inserted well into the fruit, and readings from this are used for determining when the heaters should be lighted, the thermometer is somewhat similar to a clinical thermometer It is asserted that from 85 to 90 per cent. of the fruit is screened from the sky by foliage. The freezing-point of the juices of the fruit varied from 26° to 28·5° F., and examples are given of the temperature falling to about 24° F. before the juice began to freeze. The amount of damage to mature fruit depends largely on the thickness of the rind.

LEECHES FROM KASHMIR.—Dr. J. Percy Moore describes (Proc. Acad. Natural Sci., Philadelphia, vol 76, pp 343-388, 1924) the first collection of leeches from Kashmir, and it is interesting to note that the following species are included—*Glossiphonia complanata*, *G weberi*, *Hemiclepsis marginata* (subsp. *asiatica* nov.), *Erpobdella octoculata*, and *Dina weberi*. The first, third, and fourth of these are widely distributed and abundant Eurasiatic species, the first being even holarctic The remaining two are characteristic Indo-Malayan forms. Dr. Moore also gives an account of a collection of leeches from eastern China.

CRITICAL STUDY OF LEIDY'S ACANTHOCEPHALA.—Dr H J. Van Cleave has investigated the specimens of Acanthocephala in the Leidy collection deposited in the University of Pennsylvania and in the Academy of Natural Sciences, Philadelphia, and gives a critical review of this important material (Proc Acad. Natural Sci., Philadelphia, vol. 76, pp. 279-334, 1924). He states that of the North American genera of Acanthocephala known at the present time fully half had come to the attention of Leidy. The author gives in tabular form a list of the specific names used by Leidy and the valid or corrected names, pointing out at the same time that Leidy's work was characterised by great care and that some of his difficulties in identification were due to the incomplete description of European species. Twenty-one species are represented in the collection and they are arranged under thirteen genera.

EXPERIMENTAL STUDIES ON *DIBOTHRIOCEPHALUS LATUS* IN MAN.—G. Z. L le Bas (*Journ. Helminthology*, vol. 2, No. 4, 1924) publishes observations on three persons who infected themselves with this tapeworm by swallowing the plerocercoid stage obtained from pike taken from the Lake of Neuchâtel. Case A was infected with three worms which attained maturity (as evidenced by finding the eggs in the fæces) in 20 days; case B was also infected with three worms which reached maturity in 14 days, while the single worm in case C took 26 days to reach sexual maturity. The average length of the three worms from case B after 99 days was 22 feet, and the number of eggs present about this time per gram of dried fæces was about 7 millions in case A, and in case B 12¼ millions about the 90th day of infection and 17½ millions on the 99th day. Intestinal disturbance is associated with the period of maturation of the worm, but, apart from this diarrhœa in the early stages, infection with three Dibothriocephalus for so long as nine months does not necessarily give rise to any symptoms which would suggest the presence of the parasite. No appreciable anæmia was produced, nor was there a definite diminution of the red blood corpuscles. Leucocytosis and an increase of the polymorphonuclear cells was observable in a slight degree, especially early in the infection.

CLASSIFICATION OF IGNEOUS ROCKS.—E. T. Hodge proposes a new form of classification for igneous rocks in a Publication (vol 2, No 7, 1924) of the University of Oregon. The older classifications are ably summarised and criticised. Single plane arrangements have hitherto been far from satisfactory. Winchell employed three planes exhibiting relative degrees of "alkalinity"; Holmes used five planes, dividing rocks according to Shand's saturation principle; and Johannsen used a solid double tetrahedron, thus introducing obvious difficulties in presentation. It is claimed that the new method

avoids the defects of previous attempts. The first division is into four *classes* based on the percentage of felspars plus felspathoids. Each of these is divided into seven *ranges* according to the principle of saturation Further subdivision is into nineteen *orders* depending on the ratio of orthoclase to the various types of plagioclase. The division thus makes provision for a large number of different types of rocks, all of which can be represented quantitatively in a plane circle on a single sheet. Four segments of the circle take the classes Six smaller concentric circles give seven spaces for the ranges, and each segment is divided into nineteen smaller segments by radial lines to take the orders. So far only mineral composition has been considered, though the author makes the remarkable claim that, whether chemical or mineral composition be given, the rock will fall into the same division of the classification. Texture next requires attention, and to meet the formidable difficulties inherent in any cross classification of so variable a factor, it is suggested as a simple expedient that to each a symbol be given which could be added to the rock name as a subscript. As a mental prop a classification of this kind may have its use, but petrology has now passed the stage in which it would have been considered as a contribution to the development of the subject.

UNITED STATES COASTAL SURVEYS.—The Report of the United States Coast and Geodetic Survey for the year 1923–24, published by the Department of Commerce, Washington, contains a long record of useful work and a review of the present state of the various hydrographic, geodetic, and magnetic surveys now in hand. Among the surveys of the year the progress in Alaska was very notable. So far the work has been mainly in the waters of southern Alaska, but it is spreading northwards to the shores of Bering Strait. A new survey of the waters of the Philippines is nearly complete, and a survey of the Virgin Island waters is half finished. The provision of several new survey vessels has greatly facilitated the work of the department. The results of experiments with the sonic depth-finder on the *Guide* are promised in a separate report. The apparatus is to be used in extending the survey of Pacific coastal waters to the 1000-fathom line The Report is furnished with numerous maps showing the present state of surveys.

FLOTATION METHOD OF CLEANING COAL.—In the Bulletin de la Société d'Encouragement pour l'Industrie Nationale of January recently received, Charles Berthelot describes fully the process of cleaning fine coal by the flotation method, and points out the advantages to be derived therefrom. He gives an account of the plant employed at the Fiscal Mines of the Netherlands, devised by the chief engineer, Mr Kleinbentink, which differs from the well-known plant of the Minerals Separation Company in that the frothing chamber is circular in plan surrounded by a circular chamber for collecting the froth. In Holland it has given very satisfactory results, and the working costs are only half of those incurred by the Minerals Separation Company, namely 1·32 francs as against 2·66 francs per ton. The mines in question are dealing with 100,000 tons per annum of coal slimes, the ash content of which is reduced from 30 per cent. to 8 per cent., the floated coal being well adapted to the preparation of either metallurgical or foundry coke or briquettes. It is stated that the cost of a plant to treat 50,000 tons of coal slimes per annum amounts to 200,000 francs and can make a gross profit of 850,000 francs per annum. The article makes no reference to the means employed for removing the water from the froth in the Dutch plant described.

DIAMOND HARDNESS TESTING MACHINE.—In the Brinell hardness test, the steel balls hitherto used for making measurable impressions under load were themselves deformed when indenting very hard specimens. The results fell off in accuracy at an early stage Messrs Vickers, Ltd., have now produced a machine, employing a small diamond pyramid (included angle 136°) as indenter, which gives trustworthy readings upon the very hardest steels. The use of a pyramid is scientifically sound, and the "hardness numbers" are similar to, if not identical with, those of the universally adopted Brinell scale. The indentations are very small, and the machine meets almost all the demands of a modern metallurgical hardness tester, for (*a*) the load is applied at a constant rate and for a constant time; (*b*) the load may be varied from 10 to 100 kgm to suit the sample being tested; (*c*) thin sections, *e.g.* hardened safety razor blades, may be tested; and (*d*) there is no damage to finished work. The machine is suitable for research and general use, as loading is automatic and the measuring operations are simplified A microscope is swung into position directly over the specimen, and knife edges in the eyepiece are brought up to opposite corners of the indentation The reading then appears externally in actual figures

SOLUBILITY AT HIGH PRESSURES.—A method of determining solubility at high pressures, by means of measurements of electrical conductivity, is described by Messrs. E. Cohen and J. C van der Bosch in the *Zeitschrift fur physikalische Chemie* of January 20 Thallous sulphate was employed, as the alteration of volume on solution is large, and a considerable alteration of solubility with pressure was to be expected. Measurements were made at various concentrations to find the relation between concentration and resistance at high pressures. To determine the maximum solubility, at 1500 atmos. for example, weighed quantities of thallous sulphate and water were taken, which would give a slightly oversaturated solution at 30° C; this was placed in a suitable resistance vessel in a compression bomb, which could be constantly shaken by means of a mechanical arrangement driven by an electric motor. The pressure was raised to 1800 atmos., and the salt dissolved completely, when the pressure was reduced to 1500 atmos., without shaking, a supersaturated solution was obtained the resistance of which was determined After long shaking the excess of salt gradually crystallised out, the resistance rising and finally becoming constant. From these measurements it was possible to find the amount of salt in the saturated solution. The method takes a long time, but the results obtained agree well with those arrived at by other observers, using the direct method.

ZINC OXIDE INDUSTRY.—An account of the zinc oxide industry by Dr. N. F Budgen appears in the *Chemical Trade Journal* for February 20. Zinc oxide has been known from the times of antiquity; the ancients called it *tutia*, and the alchemists referred to it as *nix alba*, "philosophical wool," or flowers of zinc Courtois recommended its use as a paint in 1770, and in 1781 he commenced the large-scale manufacture of the substance. The Wetherill process in the United States involves the reduction and distillation of zinc from oxidised ores mixed with a certain amount of anthracite to act as reducing agent. The vaporised zinc is quickly oxidised, and with the gases of combustion is drawn from the furnaces and cooled in a system of flues and chambers, finally passing into a series of muslin bags which act as filters, allowing the gases of combustion to escape, at the same time retaining the condensed zinc oxide. The difficulties and drawbacks in the Wetherill process are discussed.

The Molecular Mechanism of Capillary Phenomena.[1]

By N. K. ADAM

AN important question for the theory of capillarity is this: Is it necessary, in order to explain the observed phenomena, to conclude that there is, in the surface of a liquid, any differentiation of the molecular arrangements and forces from those prevailing in the interior, of such a nature that there is a skin possessing a tension parallel to the surface? Many writers appear to assume that, because the free energy associated with each unit of area of the surface is most conveniently replaced in calculations by a tension parallel to the surface, there must be some special structure in the surface which produces this tension physically. Although any free energy resident at the surface may mathematically be considered as the product of a "surface tension" and the area, there is no justification in this fact for concluding that the molecular arrangements and forces at the surface resemble those in a stretched membrane. Indeed, probably all attempts made to explain the molecular structure of surfaces, which have assumed such a contractile mechanism, have been complete failures.

Recent work on films of fatty material, one molecule thick, on water surfaces, has been satisfactorily interpreted in terms of molecular structure by regarding the molecules of the film simply as small floating objects, which attract one another when close enough, and repel when quite closely packed; thus assuming only the ordinary properties of molecules. If a film of this nature is confined by barriers to a given region of the surface, the force on the barriers is regarded as a compression on the floating film. Very striking analogies between the structure of the films, and the structure of matter in three dimensions and in solid, liquid, and gaseous states, have been revealed on this assumption; while if the force on the barriers had been treated as the difference between two tensions, those of the clean and contaminated water surfaces, no progress could have been made in unravelling the molecular structure. The two ways of regarding the films are mutually exclusive, and the success of the "compression theory" casts much doubt on the reality of any structure in the surface which produces tension.

A liquid probably has a well-defined surface, a surface of water forms a satisfactory support for films one molecule thick, which are as closely packed as matter in solid or liquid form, and will withstand lateral compression of one or two hundred atmospheres, calculated on their thickness. Only a liquid of density practically the same at the surface as in the interior could form a stable support for such films. The rarefied transition layers between liquid and gas, discussed by Van der Waals, can scarcely be conceived as able to bear these condensed films.

The surface energy of all liquids, and the tendency to diminish the surface to a minimum, are due in the following way to the molecular cohesion. In the interior, a molecule is attracted equally in all directions by its neighbours, at the surface the attraction outwards is lacking, and every surface molecule is therefore attracted inwards. Simple cohesive forces will produce no other net force on the surface molecules. This is sufficient to cause molecules to leave the surface more frequently than they reach it, and consequently, since the molecules occupy a definite area in the surface, the surface diminishes. The free energy of the surface is the work which must be done to bring the number of molecules requisite to form unit area, to the surface, against this inward force.

There are two other arguments sometimes cited as evidence of the existence of a surface skin; the floating of a heavy solid object on the surface of a liquid, and the spreading of one liquid on another. But consideration of possible molecular structures for the skins which would cause a liquid surface to diminish, and would resist perforation by a solid body, show that opposite qualities would be required in the two cases. The skin tending to contract the surface would essentially expel molecules from itself; but the skin which would act as a support for a heavy body would need such cohesion that it would be most unlikely, left to itself, to diminish indefinitely.

An experiment of Osborne Reynolds[2] renders it very probable that spreading of oil on water is due to an outward thrust from the oil drop, instead of a pull from the water surface. Oil placed on a dusted surface of clean water pushes the dust back as it advances, only immediately at the edge of the advancing oil, there being obviously no contractile motion over the rest of the water surface. A force which can produce this expansion in the form of a thrust from the drop is not far to seek. The molecules of the water are in constant thermal agitation, and the horizontal components of this motion act in the required direction, and will carry out the molecules of oil along the surface, if they are sufficiently adherent to the water molecules to share in their motion, and are not more attracted by the oil than by the water. Evidence of the importance of these thermal motions parallel to the surface is also given by the behaviour of the monomolecular films, as the temperature rises. It is found that, when the temperature is high enough, the disruptive effect of the agitation overcomes the lateral attraction between the film molecules and causes expansion to take place, the expanded film being analogous to a two-dimensional gas.

These thermal agitations also account for the diminution of the free surface energy, or "surface tension," of all liquids with temperature. If the surface is warmer on one side of a floating object than on the other, the intensity of the horizontal bombardment on this object is greater on the warm side than on the cold. We need not regard the observed motion towards the cold side as due to the attraction of the surface skin being less on the warm than on the cold side. By reason of this difference in intensity of bombardment, work must be done to increase the area of the cold surface at the expense of that of the warm, and the "surface tension" of the cold surface is greater than that of the warm.

It is well known that the pressure is greater on the concave side of a curved liquid surface than on the convex, and that the amount of this excess pressure is $\eta\left(\frac{1}{R_1}+\frac{1}{R_2}\right)$ where η is the "surface tension" and R_1 and R_2 the principal radii of curvature of the surface. The amount of this excess pressure can be deduced simply from the fact of a free energy η per unit area of the surface, by considering a variation of the area of surface, keeping the volume constant. The fact that its magnitude is the same as if the surface were covered by a membrane of tension η is not evidence as to the molecular mechanism by which the pressure is produced.

At the free surface, the attractions perpendicularly

[1] Based on a lecture delivered to the Physical Society of Sheffield, on October 28, 1924.

[2] Works, vol. 1, p. 410. Brit. Ass. Rep., 1881.

inwards on the surface molecules produce a pressure on the underlying molecules, the "internal pressure." Fig. 1 will show that on a plane surface the forces producing this pressure are parallel; on the surface convex outwards they are convergent and therefore the pressure is greater; on the surface concave outwards they are divergent, giving a smaller pressure than under the plane surface. Thus the unbalanced perpendicular attraction on the surface accounts for

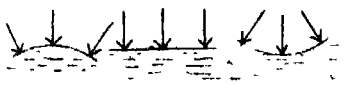

FIG. 1.

the pressure under a curved surface, without the assumption of an elastic skin

Where the surface is the surface of separation between two liquids, or between a solid and a liquid, the attractions on the surface molecules of each phase towards the interior of that phase are modified and usually less than at a free surface; but the only net force on the surface molecules is an attraction away from the boundary. The equilibrium between the forces of attraction at the interfaces of solid, liquid, and gas, in contact, results in the angle of contact (Fig. 2). If W be the work per unit area required to

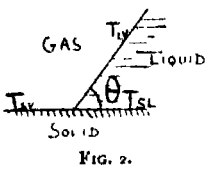

FIG. 2.

separate the solid from the liquid perpendicularly, then

$$W = T_{SV} + T_{LV} - T_{SL} \quad . \quad . \quad (1).$$ [8]

W may be called the adhesion of the liquid for the solid. Further, the equation

$$T_{SV} = T_{SL} + T_{LV} \cos\theta \quad . \quad . \quad . \quad (2)$$

may be obtained by taking account of the changes of area involved in a virtual displacement of the line of contact of solid, liquid, and gas. Hence

$$W = T_{LV}(1 + \cos\theta). \quad . \quad . \quad . \quad (3).$$

By (3), a zero angle of contact indicates that the adhesion of the liquid for the solid is equal to the cohesion ($2T_{LV}$) of the liquid for itself; 90° shows the adhesion to be half the liquid cohesion, and 180° would indicate no adhesion.

When there is motion of the liquid over the solid surface, the angle of contact is different. If the liquid is advancing, the angle is greater, if receding, it is less, than the equilibrium value. The amount of this difference, sometimes called the hysteresis of the angle of contact, probably depends more on the smoothness of the surface than on its chemical characteristics. For a rough surface of paraffin wax, for which the equilibrium angle is 104° 30′, the difference between advancing and receding angles may amount to nearly 60°; and on such a surface it is practically impossible to obtain the equilibrium angle, within several degrees. However, on a wax surface which had been turned in a lathe, Ablett [4] obtained consistent results, within a few minutes of arc, for the equilibrium angle. Mr. G. Jessop has pointed out that this "hysteresis" is probably due to the friction of the liquid on the solid surface, acting to oppose the motion. If the frictional force is F, then for advancing motion, equation (2) becomes

$$T_{SV} - T_{SL} = T_{LV} \cos\theta_A + F,$$

and for receding motion,

$$T_{SV} - T_{SL} = T_{LV} \cos\theta_R - F;$$

hence the angle must be greater for advancing than for receding motion. Also,

$$2(T_{SV} - T_{SL}) = 2T_{LV} \cos\theta = T_{LV}(\cos\theta_A + \cos\theta_R),$$

therefore

$$2\cos\theta = \cos\theta_A + \cos\theta_R,$$

an equation approximately verified by Ablett, for his surface of paraffin wax.

This surface friction probably explains the third of the phenomena sometimes attributed to the surface skin, the floating of a solid object on a liquid of less density. In Fig 3, the line of contact between the liquid and solid surfaces will not move unless the part of the weight of the solid not supported by the

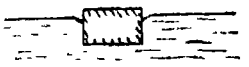

FIG. 3.

buoyancy of the liquid exceeds the frictional force F. In this way a substance heavier than water can float on the surface, as any depression of the line of contact below the level of the surface requires an increase in area of the liquid surface, if the angle of contact is greater than 90°, and requires the performance of work.

The sequence of events in the rise of a liquid in a capillary tube suddenly brought into the liquid will be, first, the setting up of an angle of contact (acute for a rising liquid), second, a diminution of pressure under those regions of the surface where there is disturbance due to the angle of contact, third, motion of the liquid upwards, by reason of this diminution of pressure, first probably to complete the meniscus, and then as a whole up the tube If the tube is dry, the liquid is advancing and the angle of contact will be greater than the equilibrium angle, the radius of curvature of the meniscus will be greater, the pressure deficiency under the curved surface will be less, than the equilibrium, and the liquid will not reach the equilibrium height in the tube, this is a well-known experimental fact. Washburn [5] has shown that the rate of movement of liquid in a capillary tube is in accordance with the value of the capillary pressure, and the viscous resistance to flow, but this does not serve to distinguish between this explanation and one based on the idea of "surface tension," since the capillary pressure is numerically equal to what would be caused by a membrane in tension. Rideal [6] obtains the same differential equation for the motion of the liquid, considering the force driving the liquid as a tension of magnitude $2\pi r\eta$, where r is the radius of the tube, and the liquid wets the walls perfectly.

In general, where the phenomena considered are merely consequences of the fact of potential energy in the surface, the term "surface tension" can legitimately be employed; but where the molecular mechanisms producing the phenomena are under consideration, the term is apt to be misleading, as it suggests some kind of contractile skin in the surface, the existence of which is very unlikely.

[8] Dupré's well-known equation. Equation 3 has been obtained by Edser, and a similar equation is obtainable from Laplace's theory, considering the attractions between particles of liquid and solid, and liquid and liquid.

The Syrian Arc.

THE Syrian Arc is the name proposed by Dr. E. Krenkel for a mountain chain which can be traced around the south and east of the Levant from Tunis to the Taurus The name is given in a short but important paper ("Der Syrische Bogen," *Centralblatt für Mineralogie*, 1924, No. 9, pp 274-281, and No. 10, pp 301-313) which correlates the mountain movements which have determined the position of the south-eastern Mediterranean. According to Dr. Krenkel, this mountain chain begins to the west in Tunisia, where there are two sets of fold mountains The predominant set belong to the Atlas System and its members trend to the north-east. The set in southern Tunis trends east and west and is obviously a distinct mountain group from the Atlas.

According to Dr Krenkel, this southern set is the westernmost element of the Syrian Arc It is cut off by the Great Syrtis from Cyrenaica. Dr Krenkel, from the writer's work on the geology of Cyrenaica, interprets its plateau as one of the inner members of the Syrian Arc In Egypt this arc is represented by three fold ranges, those of Abu Roasch, Wadi Araba and Quena. It continues with a trend to the east-north-east, across the deserts of northern Sinai, where it has been determined by Messrs. Moon and Sadek The Egyptian and Sinaitic members of the Syrian Arc are separated by the Gulf of Suez

According to one view, the Clysmian valley of Dr. Hume, which includes that gulf, is the direct continuation of the Rift Valley of the Red Sea According to another view, it is a synclinal. According to Dr Hume, it is due to a combination of faulting and a series of Erythrean folds. Dr Krenkel supports the first of these interpretations as the Gulf of Suez lies in a rift valley which has broken across the Syrian Arc nearly at right angles, and the structures which have been interpreted as due to a series of Erythrean folds Dr. Krenkel explains as due "to the tossing and tilting of unclinal sedimentary blocks which appear on the floor of the rift valley" He denies the existence of Erythrean folds due to pressure in a westerly or easterly direction.

From Sinai the Syrian Arc passes north; it is bounded westward by a series of steps down to the Mediterranean and eastward, according to some accounts, by flexures. Dr. Krenkel represents these flexures as fractures which have broken across pre-existing folds. He attributes the topography of this area to a combination of an older folding with the younger rift valley fractures In Syria, however, where the structure has been represented by Diener and most of his successors as determined by simple block structures, Dr. Krenkel insists on the importance of folds In middle Syria, the Lebanon on the west is separated by the great valley of the Bakaa from Mt. Hermon and the Anti-lebanon. This valley he attributes to a down-fold lasting from the end of the Cretaceous to the Upper Miocene; but the Bakaa in its present form he describes as a rift valley made by Pliocene fractures. The Damascus Arc is a branch from the Syrian Arc and is marked by the presence of the only overfolding recognised by Dr. Krenkel anywhere along the Syrian Arc, it happened there to a slight extent owing to the pressure of the Damascus Arc against the northern edge of the Arabian Foreland Farther north the Syrian Arc ends against the cross folds of the Taurus The line of separation is defined by Dr Krenkel as the Afrin line which divides the African element from those of Asia Minor.

The Syrian Arc was upraised by folding in three stages: the first movement was in the uppermost Cretaceous (Upper Danian); the second in the Lower Miocene; the third and most important was in the Upper Miocene The crumpling was due, according to Dr Krenkel, to pressure from the south and east toward the Mediterranean. It was therefore in the opposite direction to that in the Dinaric-Taurus Arcs, which extend along the eastern side of the Adriatic, through Greece and the Archipelago to the southern chains of Asia Minor The general course of the Syrian Arc conforms closely to that of the Dinaric and Taurus Mountains, and both of the mountain arcs moved toward the great depression of the Eastern Mediterranean which lies between them.

J. W. GREGORY.

Permanent Magnets.

MR. S. EVERSHED read an important and valuable paper on permanent magnets to the Institution of Electrical Engineers on March 19. The paper gives the results of many years' research, and ought to prove of immediate value in improving the quality and cheapening the cost of high-grade permanent magnets In 1616 Barlowe wrote concerning the mediæval art and mystery of magnet making—"The compass needle, being the most admirable and useful instrument in the whole world, is so bungerly and absurdly contrived as no other." Although the permanent magnet has become an indispensable adjunct of modern engineering, yet industries rooted in tradition are generally backward, and magnet making is no exception

The hardening of iron and the making of steel were probably discovered accidentally. Metallurgists have found that ordinary pure iron exists in various allotropic forms depending on the temperature. At ordinary temperature it is called Alpha iron and is the commonest of all metals. Its specific heat at 0° C. is 0·1055 precisely, which is in excellent accord with theory. This specific heat gradually increases until about 750° C. The author calls this the precursor effect, as it indicates that the heat is not all expended in raising the temperature; some of it is doubtless expended in effecting a change of some kind in the structure of the iron. At about 770° C. Alpha iron begins to change into Beta iron, and the transformation is practically complete at 810° C.

Alpha iron is magnetic, Beta iron is entirely non-magnetic. As the molecule of Beta iron must be quite different from that of Alpha iron it is practically a new element. Throughout the narrow zone of temperature of 40° C Alpha and Beta molecules can exist together, and this explains the loss and recovery of magnetism in iron as shown by experimental curves. At between 918° and 920° C. Beta iron is converted into Gamma iron, and at between 1404° and 1405° C. Gamma iron becomes Delta iron, its specific heat suddenly increasing by 50 per cent. At 1528° C. pure iron melts. Assuming that specific heat is inversely proportional to atomic weight, it would follow that these varieties of iron should have atomic weights of about 56, 37, 41, and 27, which are the atomic weights of iron, chlorine, calcium, and aluminium. The molecules have not changed successively into the molecules of these elements, but they must have done something equally revolutionary.

The carbides used in manufacturing magnet steels dissolve freely in Delta, Gamma, and Beta iron, but

these kinds of iron are all non-magnetic. To make a magnet the steel must be magnetic, and consequently in the Alpha state. It is necessary, therefore, to heat the iron until it is in the Beta or Gamma state, dissolve a quantity of carbide in it, and then by plunging it into cold water make it return quickly to the Alpha state.

Nowadays carbon steel is seldom used for permanent magnets. Tungsten magnet steel is made similarly to carbon magnet steel, but half the carbide of iron is replaced by carbide of tungsten, the total content of carbon remaining unchanged The effect of replacing part of one solute substance by another is to increase the magnetic coercive force from rather less than 50 to slightly more than 70 When cobalt is used instead of tungsten the coercive force is increased to 180 From the point of view of the manufacturer, tungsten steel is generally the most attractive Carbon steel is 60 per cent more costly, and cobalt steel costs three or four times as much. Cobalt steel withstands demagnetising forces much more effectively than tungsten steel. If two permanent straight magnets, one of tungsten steel and the other of cobalt steel, were subjected to demagnetising forces equal to 20 per cent. of their coercive force, the tungsten magnet would lose 14 per cent. of its strength, but the cobalt magnet would only lose 3 per cent

The author has made many experiments on the loss of the coercive force in all kinds of " permanent " magnets. In a cobalt magnet, for example, the initial coercive force was 180, but after 4·4 years it had fallen to 161·8. The continued falling off in the coercive force of hardened magnet steel is attributed to the passage of carbide molecules out of solution Immediately after the hardening, the coercive force decreases by about 7 per cent. in the course of the first hundred hours, but after a year the rate of decay seems to settle down to a small steady value The author calculates that the whole of the surplus carbide in cobalt steel might pass out of solution in about seventy years, the steel then being completely softened. He has noticed, however, a seasonal oscillation in the value of the coercive force, the reason of which is still unexplained.

When manufacturing steel containing tungsten or cobalt for use in making permanent magnets, the greatest attention has to be paid to the heat treatment. The experiments described prove conclusively that if tungsten steel be heated to any temperature between 750° C. and 1214° C., and kept at this temperature for an appreciable time before hardening, its magnetic properties are weakened, the weakening increasing with the length of time the steel has been kept at the high temperature The deterioration of the steel goes on most rapidly when the temperature is 950° C. At 1200° C. the spoiling of the steel goes on very slowly, the coercive force falling only 0·4 units per hour. At 1240° C., however, which is only 26° above the danger zone, restoration of coercive force takes place at the rate of 15 units a minute. It is obvious, therefore, that great attention has to be paid to the temperature to which the steel is heated, before hardening.

This paper is a sequel to one the author read to the Institution in 1920, and together they give a very complete account of the modern theory and practice of magnet making. The results obtained by the British Scientific Instrument Research Association on the possibility of making magnets of complicated shapes by casting them with molten metal and then subjecting them to a suitable heat treatment are described. The method appears to be very promising and already cast magnets are on the market.

University and Educational Intelligence.

CAMBRIDGE —Particulars are now available of the Pinsent-Darwin Studentship in mental pathology, founded in 1924 by Mrs Pinsent and Sir Horace and Lady Darwin for promoting research into any problem which may have a bearing on mental defects, diseases or disorders. The Studentship is of the annual value of about 200*l.* and is tenable for three years in the first instance Candidates may be of either sex, and need not be members of the University of Cambridge. Applications must be sent before May 1 to the Secretary, Pinsent-Darwin Studentship, Psychological Laboratory, Cambridge

EDINBURGH —The following are among the honorary degrees to be conferred in July —LL.D. Brigadier-General the Hon Charles Granville Bruce, chief of the Mount Everest Expedition, Prof A S Eddington, Plumian professor of astronomy and experimental philosophy in the University of Cambridge, Prof Robert Muir, professor of pathology in the University of Glasgow, Principal C G. Robertson, University of Birmingham, Sir Harold J Stiles, emeritus professor (clinical surgery) in the University of Edinburgh

LEEDS —Mr J. Gordon has been appointed lecturer in bacteriology in succession to Dr Ross resigned An honorary demonstratorship has been instituted in the Department of Zoology, and Mrs H W. Swift appointed thereto

LONDON —In commemoration of the donation of 105,000*l.* made in 1914 by Sir Hildred Carlile, Bart, to the Endowment Fund of Bedford College, it has been resolved that the University chairs of English literature, Latin, botany, and physics tenable at the College shall henceforth be entitled the " Hildred Carlile " chairs

The following doctorates have been awarded: *Ph.D.* (*Science*), Mr. K C. D Hickman (Imperial College—Royal College of Science) for a thesis entitled " Studies in Adsorption, with special reference to the Washing of Photographic Products," and other papers, and Mr D. F. Stedman (University College) for a thesis entitled " The Liquid-vapour Equilibrium of the System Glycerine-water "; *D Sc.* (*Physics*), Mr. F Simeon (University College) for a thesis entitled " 1 The Carbon Arc Spectrum in the Extreme Ultra-violet: 2 Note on the Striking Potential necessary to produce a Persistent Arc in Vacuum," and other papers, and Mr. B. W. Clack (Birkbeck College) for a thesis entitled " On the Study of Diffusion in Liquids by an Optical Method "

ST ANDREWS —The Senatus Academicus has resolved to confer the honorary degree of LL.D. on the following, among others: Sir William Bragg, Fullerian professor of chemistry at the Royal Institution, and Director of the Davy-Faraday Research Laboratory, Prof. F. G. Donnan, professor of inorganic and physical chemistry in the University of London; Prof Etienne Gilson, professor of philosophy of the Middle Ages, Sorbonne, University of Paris, Mr. R. W. T. Gunther, fellow of Magdalen College, Oxford.

A COMPETITIVE examination for two scholarships at the Household and Social Science department of King's College for Women, namely, the Carl Meyer, 80*l.* a year for three years, and the Minor College, 40*l.* a year for three years, will be held on May 21. The latest date for the receipt of entry applications is May 18. They should be sent to the Secretary of the department, Campden Hill Road, W.8.

THE next election to the research scholarships of the Grocers' Company for the prosecution of original research in sanitary science will take place in May, and applications for them are invited until April 14. The scholarships are each of the annual value of 300*l.*, plus an allowance for apparatus and other expenses. They are tenable for a year, with the possibility of renewal for a second or a third year. Applications, upon a form to be provided, should be sent to the Clerk of the Company, Grocers' Hall, E.C.2

THE second session of the summer school for post-graduate mathematics, organised by the Extra Mural Department of the University of Manchester, will be held at University College, Bangor, on August 24–September 5. The object of the school, which is recognised by the Board of Education, is to afford facilities for advanced study in mathematics to teachers and others who have read mathematics for a university degree. The following three alternative courses are proposed: (*a*) Atomic structure and the quantum theory, by Prof. Sydney Chapman (Imperial College of Science, London); (*b*) theory of functions, by Prof. L. J. Mordell (University of Manchester); (*c*) higher geometry, by Mr. H. W. Richmond (King's College, Cambridge). Particulars may be obtained from Miss D. Withington, The University, Manchester. Application should be made at an early date, as the holding of the courses depends to some extent upon the number of applications received.

IN any college where a large staff is employed, the duties and interests cover a wide variety of subjects, and the results of research work are often scattered over technical journals and the proceedings of many societies, a procedure which fails to provide an adequate view of the work of the college as a whole. The authorities of the Royal Technical College, Glasgow, have been considering this matter, and have resolved to publish an official journal, which will contain records of the research work done in the college, and thus prove an incentive to junior workers in particular. A copy of the first number of the Journal of the college is now before us, and contains records of eleven researches conducted in the college, representing chemistry, metallurgy and engineering. The name of the editor does not appear, but he is to be congratulated upon the production, and especially upon the useful feature of printing a short abstract of each paper immediately under its title. The research activities of the college may be judged by the articles which appear in this issue. These include papers on some acyl derivatives of hydrazine; the formation and constitution of certain double salts with a review and criticism of van 't Hoff's theory; radio-active substances as indicators with a study of the adsorption of lead and bismuth by ferric hydroxide and the adsorption of thorium by basic ferric acetate and by barium sulphate by this method; the hydro-ferro- and hydrofern-cyanides of the organic bases and some applications; the separation of the components of petroleum with the view of utilising this commodity as a raw material for chemical industries; the iron-carbon diagram; the copper-zinc system; the petrological and chemical examination of slag and metal samples from a basic open-hearth furnace. These papers are followed by two on engineering subjects which occupy nearly one half of the issue; the subjects are the pipe loss in steam nozzles, and turbine wheel friction, on both of which the Royal Technical College has already given authoritative papers. The last paper deals with the structure and mode of life of the sulphur-bacteria and their value as indicators of pollution. The appearance of this Journal will be welcomed alike by science and engineering workers, and cannot fail to be beneficial to research workers in the college itself.

Early Science at Oxford.

April 6, 1686. Mr. Aston communicated amendments of ye Treatise *De Moventibus in Fluido*, and Mr. Ash sent a Demonstration of the 2d and 5th books of Euclide, and ye whole doctrine of proportion done more briefly than heretofore; for both which ye Secretary was ordered to returne ye thankes of ye Society.

April 7, 1685. A very rationall Discourse concerning Weather, written some time since by Dr. Garden (by way of Letter to his Friend Mr. Scougall) was read. The Society ordered their thankes to be returned, both to Dr. Middleton and to Dr. Garden, for the communication of so considerable a piece of Philosophy. One passage in Dr. Garden's discourse deducing the Rise and Fall of Vapours from their weight in respect to that of the Air, (intimating, that ye Vapours arise, when specifically lighter, and fall when specifically heavier, than the Air). Mr. President, not denying this to be true, added hereunto, that Subterraneal heats, or other ferments, may bear some part in producing this effect; as impelling upwards those Vapours, which, being specifically heavier than the Air, fall again in a little time. An instance of which he gave in ye boyling of Water, where the vapours are forced upwards by the fire placed under the Vessell, and, having lost that impetus, which raised them, and being intensively heavier than the Air, sink down again.

A Letter from Mr. Aston mentioned a Catalogue of Rarities, brought from Ceylon, by Dr. Heerman of Leyden, and preserved according to a peculiar way known to him. A Transcript of this Catalogue is desired. The remaining half of Mr. Leewenhoeck's Letter concerns the Salts of Wine, Vinegar &c, was read.

April 8, 1684. Mr. Ballard discoursed concerning ye Magnetism of Drills, being by way of answer to a letter of Mr. Aston's on that subject, dated March ye 15th. Six or seven severall Drills were caused to be made before my face; and ye bit, or point, of every one became a North Pole, onely by ye hardning, before they ever came to be workd either in Iron, or any other Matter. That peices of plain Iron in shape like Drills (that is something long, and small,) do always change their Poles, as they are inverted (ye end downward being over ye North Pole) he finds not allways true. Mr. Hunt's experiments on drilling were repeated, but his conclusions were found not to be always confirmed. Mr. Bernard read a letter of his to Dr. Huntingdon, concerning ye place of ye fixed starrs, as treated of in severall Arabic authors, given to Merton College Library by ye Doctor.—There being some discourse concerning ye insipid tast of ye Ice of Seawater, it was queried, whether sea-water might not be sweetned, and rendred serviceable.

April 10, 1688. The Standards of the wine, corn, and Ale Gallons, kept at St. Marys, were examined by Dr. Bernard, Mr. Walker and Mr. Caswell. They were filled with Pump-water, and then weighed. The weights compared with a former experiment by this Society of the weight of a cubic foot of water, give the quantitys of these Gallons in cubic Inches, &c.

Wine—Gallon -	232 : 00	cubic Inches.
Corn—Gallon -	270 : 43	
Ale—Gallon -	280 : 15	

The variation of the Needle at Oxford July 22nd 1687 was found to be 5°20′ West.

Dr. Bernard presented the Society with his book *De Ponderibus et Mensuris Antiquis*; for which the Society returned their thanks.

Societies and Academies.

LONDON.

Royal Society, March 26.—O. W. **Richardson** and T. **Tanaka**: Regularities in the secondary spectrum of hydrogen. It has been possible to arrange 123 additional lines provisionally in 22 series. Three of these form a PQR combination. The present indications are that the moments of inertia of the emitters are spread fairly well over a range extending from the high value deduced from the PQR combination found previously to a value somewhat below the lowest value which has been deduced from Fulcher's second band. This involves an extreme variation by a factor of almost six in the moments of inertia.—S. **Chapman**: The lunar diurnal magnetic variation at Greenwich and other observatories. The systematic changes of magnetic declination at Greenwich, during the course of the lunar day, have been determined from hourly records extending over 63 years. This and other magnetic elements have been similarly studied, using shorter series of data, for the observatories of Batavia, Zikawei, and Pavlovsk. The character and magnitude of the lunar daily changes depend on the following factors: the position of the sun relative to the moon, the position of the sun relative to the equator, the distance of the moon, the sunspot epoch, and the general state of magnetic activity upon the earth—the latter being connected with particular disturbed regions on the sun's surface. The lunar daily magnetic variation varies much less with sunspot epoch, and much more with the magnetic activity, than does the solar diurnal variation. It is concluded that the lunar influence on the earth's magnetic field, exerted through the agency of the lunar tide in the earth's atmosphere, is most efficient in the polar regions.—H. T. **Flint**: A general vector analysis with applications to electrodynamical theory. The vector analyses in use, as a rule, are concerned with quantities represented by straight lines, and the space to which they are applicable is Euclidean. An account is given of an analysis in which a vector is represented by

$$\delta a' = \sum_n i^n \delta x^n.$$

The vector is of infinitesimal length and δx^n represents a component measured in any system of co-ordinates. In any kind of space, Euclidean or not, in which a point B has co-ordinates $(\delta x^1, \delta x^2, \ldots, \delta x^n)$ with respect to A we shall regard $\delta a'$ as denoting a definite quantity, whatever the system of co-ordinates. In this space we shall suppose the geodetics unique and shall regard the geodetic arc joining A and B as the geometric representatives of the vector $\delta a'$. So far as possible the notation will be similar to that of Gibbs' vector analysis. The notation may be applied to space of any dimensions, but four-dimensional space is taken as fundamental. In many cases it is possible to employ a notation that leaves the formulæ of ordinary vector analysis almost unchanged, and formulæ of the restricted principle can be carried over to the general principle by merely applying rules of generalised vectors.—Miss M. O. **Saltmarsh**: The spectra of doubly and trebly ionised phosphorus (P III and P IV). The series system in the spectrum of doubly ionised phosphorus is a doublet system in accordance with the spectroscopic displacement law. Three members of the triplet series of the spectrum of trebly ionised phosphorus have been identified. For three groups of elements, each having its own characteristic electron structure, the sharp terms are greater than the diffuse terms with the same Rydberg number for the neutral and singly ionised element, but for higher stages of ionisation the diffuse terms are greater than the sharp.—D. M. **Wrinch** and J. W. **Nicholson**: Laplace's equation and the inversion of surfaces of revolution.—T. R. **Merton** and J. G. **Pilley**: On experiments relating to the spectrum of nitrogen. When helium at about 30 mm. pressure containing a very small quantity of nitrogen is excited by feebly condensed discharges, the arc spectrum of nitrogen is developed, and under these conditions is completely isolated from the spark spectra. The arc spectrum of nitrogen is not developed in the presence of an excess of argon under the same conditions in which it appears in the presence of helium. Special precautions have to be taken to ensure the purity of the gases. When nitrogen is excited by electron impacts there appears to be a direct transition as the energy of the impacts is increased from the negative band spectrum to the spark spectrum, which would imply that the rupture of nitrogen molecules is generally into ions rather than neutral atoms.—T. H. **Havelock**: Studies in wave resistance; the effect of parallel middle body. The ship is altered by inserting varying lengths of parallel middle body between the same bow and stern. The main problem is the study of the equivalent wave-making length of the ship, and its variation with velocity and with the length of parallel middle body.—T. **Tanaka**: Wave-lengths of additional lines in the many-lined spectrum of hydrogen. Some 560 new lines in the secondary hydrogen spectrum have been measured. Incidentally it was necessary to make measurements of a considerable number of lines in the oxy-hydrogen band spectrum.—H. S. **Taylor**. A theory of the catalytic surface. A catalytic surface seems to be composite, of atoms in varying degrees of saturation in a crystal lattice. The saturation varies from that in a plane surface to those which are only held to the surface by a single constraint. It is by this constraint that these outermost atoms differ from gaseous atoms. Thus several molecular species, for example, hydrogen and an unsaturated molecule, may be attached to the same atom of catalyst.—E. F. **Armstrong** and T. P. **Hilditch**. A study of catalytic actions at solid surfaces. Pt. XII. Some observations relative to those particles of a catalyst which participate in chemical change. The rate of decline of activity of several nickel catalysts in the presence of varying concentrations of impurities characteristic of natural fatty oils has furnished evidence supporting Taylor's hypothesis (*v.* above). The active nickel atoms seem to be actually detached from their neighbouring metallic atoms during the moment in which catalytic change is effected. Pt. XIII. Some factors controlling selective hydrogenation with particular reference to certain terpene derivatives. Whilst adjacent (conjugated) ethylenic linkages are converted completely to a saturated system, two separate ethylenic linkages are hydrogenated consecutively, one double bond disappearing completely before the other is attacked: acetylenic linkages are transformed to the saturated compounds with little or no production of the corresponding ethylenic compound. Similarly, the hydrogenation of esters or glycerides of polyethylenic higher fatty acids (but not the free acids themselves) is markedly selective, and the same applies to diethylenic derivatives of the terpene series. Selective hydrogenation, observed by ourselves and by Vavon, in compounds such as carvone, limonene, citral, geraniol, and linalool, is determined mainly by (i) degree of substitution of ethylenic carbon atoms, and (ii) proximity to one or other double bond of a carbonylic or hydroxylic group. It is also deduced from these results that citral, geraniol, and linalool all contain the grouping $(CH_3)_2C=CH—$. Selective hydrogenation is of considerable importance in relation to the general theory of catalysis at a solid surface.

Royal Anthropological Institute, February 10.—J. Reid Moir: Further discoveries of Early Chellean flint implements from the Cromer Forest Bed of Norfolk. The principal site investigated exists at East Runton, where, upon the foreshore exposed at low water, is a bed, averaging 18 inches in thickness, resting upon the chalk and very strongly impregnated with salts of iron. The deposit is being slowly broken up by modern sea action, and this results in the formation of a flint bed of a precisely similar character to that present upon the foreshore at Cromer. The accumulation represents in all probability the basal layer of the Cromer Forest Bed strata From East Runton, Mr Sairn of Cromer has found a number of Forest Bed mammalian remains, including *E. meridionalis*, *E antiquus*, *Rhinoceros etruscus*, *Bison bonasus*, *Equus stenonis*, *Hyæna crocuta*, *Trogontherium cuvieri*, and numerous remains of the Cervidæ The hand-axes recorded at East Runton and Cromer show that the pieces of flint from which they were made were struck off larger masses of flint, some of which were "prepared" by flaking beforehand The evidence at East Runton establishes the fact of the occurrence of Early Chellean hand-axes in a bed at the base of the Cromer Forest Bed series of deposits, and beneath the glacial boulder clay of the Scandinavian ice-sheet, representing the second glacial period of East Anglia. It is highly probable that the specimens found upon the foreshore at Cromer were derived from a similar deposit to that still existing at East Runton.

February 20.—L. H Dudley **Buxton**: The Stoney Indians of the Bow River, Alberta. The Stoney Indians are a branch of the Dakota Sioux, from whom they separated shortly before 1640 After leaving the parent stock they joined the Crees and gradually moved in a north-westerly direction. The reserve on which they now live lies on both sides of the Bow River, in southern Alberta, at an altitude of over 4000 feet above sea-level, in the foothills of the Rockies. The country is hilly and much of it is covered with grass and, in places, low scrub. The area of the reserve is just under 140 square miles, of which fifty acres only are cultivated. The total Indian population is just over six hundred. The Stoneys are divided into three bands, which are not endogamous, but the tribe, apart from a certain admixture of Cree blood, have kept themselves very much from outside contact. They are typical Plains Indians They are very averse from agriculture, but hunt and trap at the right season and do a certain amount of trading. Although they are mostly nominal Christians, a number of the old customs, notably the Sun Dance, are still retained. The Stoneys seem in their physique to resemble closely the Siouan peoples to whom they are linguistically allied, but the most close resemblance is with the Blackfoot.

Linnean Society, February 19.—Miss A. Lorrain Smith Templeton's drawings of lichens and fungi. John Templeton (1766–1825) was well known to the botanists of his day, more especially in Ireland. Taylor states in a note to the section *Lichenes* in the "Flora Hibernica" (1836) "The foregoing account of the lichens of Ireland would have been still more incomplete, but for the extensive collections of our lamented friend, the late Mr. John Templeton of Cranmore, near Belfast." Templeton entered on the scientific study of botany in 1790. His last paper seems to have been on peat-bogs, and was contributed to the Geological Society in 1821. Several manuscript volumes of his Hibernian flora with coloured drawings are preserved in the Belfast Museum.—J. **Burtt-Davy**: The tropical element in the arborescent flora of the Transvaal. The geographical distribution of 647 kinds of trees and allied shrubby plants was discussed. About 30 per cent of these are endemic to the Transvaal and 70 per cent. are "wides." The percentage of endemics is only about two-thirds that of the endemics of all Transvaal phanerogams, suggesting that they represent types of vegetation older than many of the herbaceous types. Fully 90 per cent of the wides are tropical or subtropical; the temperate element is very small. There is evidence in a limited area of the evolution of a recent warm-temperate flora (through recent elevation of the land-surface) replacing an older tropical and subtropical flora. Islands and reefs of older floras are left stranded where climatic conditions permit them to persist; these are not homogeneous, but represent different migration periods. Several cases are cited of strictly Northern Hemisphere genera migrating into South Africa, *e.g.* Salix, Dianthus, and Juniperus, none of which can have migrated from south to north. The highway of migration southward has been the great eastern mountain-range, owing to its favourable climatic conditions (relative absence of drought periods, etc.). The great central plateau has acted as a (recent) barrier to migration, probably owing to relatively low rainfall and periodic drought.—R R **Gates**: A virescent Delphinium The numerous flowers showed little variation, the sepals were large and baggy, the spur of the posterior sepal being very short, forked at the tip, and very late in developing. The petals were very much reduced and without spurs or nectaries The androecium was unaltered and the pollen normal. The carpels were long, curved, and without stigmatic surfaces Virescence is frequently inherited as a Mendelian recessive, but often with complications, and the whole phenomenon deserves further genetic study.

Geological Society, February 25.—A. H. **Cox**: (1) The geology of Cader Idris (Merionethshire). Cader Idris is an escarpment of Ordovician igneous rocks south of the Harlech Dome. The strata have a general southward or south-eastward dip of about 40°, and the succession is given. The volcanic rocks have a much greater time-range than had been proved hitherto. The four volcanic groups are separated one from the other by sediments of thicknesses so considerable that each represents a distinct episode. The main structures have a north-east to south-west trend; but there is also a regular system of north-and-south minor folds that often cause a marked deflexion of outcrops This minor folding was operative in pre-Ordovician, Ordovician, and post-Silurian times. (2) The dissection of pitching folds. By altering the inclination of the plane of dissection across a pitching fold, outcrops can be made to take any desired curve, either concave or convex. In a pitching anticline the curves will have a downward convexity when the inclination of the dissecting plane is less than the angle of pitch, but an upward one when the direction of inclination of the dissecting plane is opposed to that of the pitch. There must, therefore, be some intermediate position in which the outcrop "curve" is such that its projection on the map appears as a straight line, and the outcrop crosses the fold without apparent deflexion. Such deceptive projections are liable to occur in districts of high relief.

PARIS.

Academy of Sciences, February 16.—A. **Lacroix**: A new type of eruptive alkaline rock.—G. **Kowalewski**: Plane groups with two fundamental infinitesimal transformations.— — **Angelesco**: Polynomials con-

nected with those of M. Appell.—André **Roussel**: Semi-continuity.—A. **Alayrac**: Study of the *vol plané* in a wind of oscillating direction and in an oscillatory wind of short period.—André **Metz**: The entanglement of the ether and the aberration of the stars. The conclusion is drawn that the aberration of the stars, as shown by experiment, is incompatible with the hypothesis of the entanglement of the ether by the earth.—Louis **de Broglie**: The natural frequency of the electron.—A **Marsat**: The verification of reflectors for the projectors of motor-cars. A description of a rapid method for determining the dimensions of the caustic curves of reflectors.—A. **Leduc**: Molecular association and the equation of state of gases.—H. **Buisson** and C **Jausseran**: The spontaneous reversal of the lines in the spectrum of neon. In a neon spectrum, lines which are simple when viewed through a short length of gas show reversal when viewed through a longer length. As a consequence of this spontaneous reversal, neon lines are not so useful in determining standards of length as has been supposed.—André **Broca** The rational mounting of stringed instruments. Modifications in mounting are described which have been proved practically to lead to improved tone and quality.—Robert **Castagné**. The radioactivity of some springs of Alpine stations (Aix-les-Bains, Challes-les-Eaux) in the Pyrenees (Bagnères-de-Bigorre) and the Cévennes (Lamalou-les-Bains, Balaruc-les-Bains, Les Fumades) and of the natural gases of Vergèze (Gard), of Hérépian and Gabian (Hérault). The results of the measurements given show the high radioactive power of the large springs at Aix-les-Bains, the important radioactivity of the waters in the Pyrenees, and the feeble radioactivity of the springs in the Cévennes and on the Mediterranean coast.—René **Audubert** and Mlle Marguerite **Quintin**: The mechanism of adsorption of ions.—F **Wandenbulcke**: The rapid estimation of sulphuric acid in waters.—A. **Kling** and Mme. A **Lassieur**. The separation of zinc and nickel by sulphuretted hydrogen Since the presence of sulphuretted hydrogen interferes with the working of the hydrogen electrode, the quinhydrone electrode and with coloured indicators, it is necessary to remove this gas completely from solutions, either by boiling or by passing air, before determining the acidity. For the quantitative precipitation of zinc as sulphide without separation of nickel the P_H must be between 1·35 and 2.—Georges **Denigès**: The alloxantin reagent, of very general application, for ferric iron.—J. F. **Durand** and R. **Naves**: The action of hydrogen peroxide on the magnesium arylamines. By using an anhydrous ethereal solution of hydrogen peroxide, phenylhydroxylamine can be prepared from C_6H_5. NH MgBr with a yield of about 80 per cent.—Paul **Jodot**: Contribution to the petrographic study of *chailles*.—Jean **Piveteau**: The age of the lowest layers of the sedimentary strata of the south-west of Madagascar, between Onilahy and Mangoky.—J. **Savornin**: The cretaceous basin of the Haute-Moulouya.—R. **Bureau** Atmospherics: their classification and their thermodynamical properties.—L. **Lutz**: The culture of Hymenomycetes fungi in artificial media.—V **Vincent**: The action of the carbonates of the alkalis and alkaline earths on the acidity of soils. The best substance for neutralising acidity in soil, in spite of its insolubility, is calcium carbonate, because it can be employed at any period without endangering the seed, and is also safer for light soils than quicklime.—Mlles. J. **Lelièvre** and Y. **Ménager**: The application to *L. flexicaulis* of the method of analysis by combustion.—L. **Hervieux**: The presence of silica in incinerated histological sections. Remarks on a note by M. A. Policard. Claim to priority.—A **Maubert**, L. **Jaloustre**, P. **Lemay**, and G. **Andreoly**: The catalytic properties of bismoxyl. The tartrobismuthate of potassium and sodium precipitates the catalase of hepatic extracts: the precipitate formed shows great activity towards hydrogen peroxide.—A. **Rochon-Duvigneaud**, E. **Bourdelle**, and J. **Dubar**: Apparatus for the determination of the visual anatomical field by the method of the trans-scleral image.—E. **Hédon**: Life without the pancreas. The effects of the suppression of the treatment by insulin in the dog completely deprived of the pancreas diabetic coma, its cure by sodium bicarbonate and insulin.—Raoul M. **May**. Relation of the nerves to degenerescence and the regeneration of the gustative papillæ.—Jacques **Pellegrin**: African fishes of the family of the Phractolœmideæ.—R. **Argaud**: The nerve terminations in human cancer.—H **Bordier**: Experiments in medullary radiotherapy This treatment has produced marked improvement, and in some cases has cured infantile paralysis. The technique is given in detail.

ROME.

Royal Academy of the Lincei, January 4.—V. Volterra in the chair.—B. **Grassi** Androphylic and androphobic gnats of Legendre.—Alfonso **Herrera**: Photosynthetic theory of the origin of life and production of organic forms with metaformaldehyde Under certain conditions formaldehyde undergoes polymerisation into metaformaldehyde, which separates in a pseudo-crystalline mass composed of microscopic cell-like and amœboid forms, the silica present as impurity in commercial formalin apparently plays a part in this phenomenon.—Ferruccio **Zambonini** and Guido **Carobbi**. Isomorphism between tervalent thallium and rare-earth metals. As would be expected from the atomic structure proposed by Bohr, the isomorphism existing between compounds of tervalent thallium and those of the rare-earth metals is of limited range.—G **Bisconcini**: Imperfect flexibility of ropes.—Mario **Crenna**. Observations on the variations in the latitude of Campidoglio.—R. **Magini**: Behaviour of empty [so-called "sandwich"] cathodes in the electric discharge at low pressure.—Paolo **Straneo**. Expression of hereditary phenomena. Deformation of materials is discussed in relation to previous stresses.—Emanuele **Quercigh**: Bismuthinite Crystallographic measurements of artificial crystals of bismuthinite lead to the axial ratios, $a : b : c = 0{\cdot}985 : 1 : 1{\cdot}004$.—Francesco **Ranfaldi**: Ethyl ester of phenyl-*p*-nitrocinnamic acid This substance forms crystals belonging to the prismatic class of the monoclinic system, the crystallographic constants being $a : b : c = 1{\cdot}65679 : 1 : 1{\cdot}83480$, $\beta = 69° 29'$; Scacchi's results for the corresponding methyl ester are modified to: $a : b : c = 1{\cdot}82871 : 1 : 0{\cdot}91775$, $\beta = 69° 29'$.—Umberto **D'Ancona** Investigations on the growth and sexual maturity of *Alosa finta* (Cuv.).—Primo **Dorello**: Function of the digitated glands in the genus Helix.—L. La **Face**. Observations on the nutrition of *Culex pipiens*.—Luisa **Volterra**. Further notes on the variability of the pelagic daphnias of Lake Nemi.—N. **Passerini**: Influence of the quality of the food on the growth of the larvæ, and on the metabolism, of *Tenebrio molitor L.*

VIENNA

Academy of Sciences, January 15.—L. **Siegl**: Communication from the Radium Institute, No. 174. The quantitative measurement of radium emanation in the guard ring plate condenser. In an attempt to make the radium standard and normal solutions superfluous, a measurement was made of the ionisation

stream which maintains the radium emanation and its successive products in equilibrium. An accurately made air-tight guard ring plate condenser was used as measuring chamber, since it alone is open to complete theoretical treatment. With regard to the three α-radiators (emanation, radium A, and radium C) only, observation and calculation gave a more than one per cent agreement beyond 4 cm plate distance, but at small plate distances a greater disagreement. An absolute measure of radium emanation and hence of radium itself can be obtained from the saturation current.—G. **Halledauer**: Communication from the Radium Institute, No. 175. A method of measuring the smallest quantities of emanation and its application to the determination of the radium content of some meteorites. The charge method can be freed from certain errors if the ionisation chamber is completely separated from the electrometer whilst charging, and only at the end and for measurement brought into brief contact with it. Emanation quantities of 10^{-14} Curie may be determined with certainty. For five iron meteorites an average of $0{\cdot}55 \times 10^{-12}$, and for five stone meteorites $6{\cdot}6 \times 10^{-13}$ gm. radium per gram, was found, in practical agreement with other authors.—H. H. **Handel-Mazzetti**: New Chinese plants, descriptions continued.—A. **Limberger**: Symbiosis of Anabæna with Azolla.

January 22.—H. **Handel-Mazzetti**: Map of a journey in the Chinese province of Hunan. H. Witt's surveys including the latitude of Wukang and of Dsingschou were utilised. Dr. H. Mazzetti as a botanist had no astronomical survey instruments, but in his survey emphasised the nature of the country within a wide range of his route, producing a general route map of scale 1 : 300,000 and maps of 1 : 100,000 near Hsikwangshan and Yunschan.

The Universities and International Relations.[1]

AT a meeting of the British Academy held on February 25, Lord Balfour, Dr. J. W. Mackail, Sir Henry Newbolt, and Sir Rennell Rodd spoke in support of the endowment fund appeal of the British Institute of Florence. The publication of reports of these speeches has attracted general attention to the enormous importance of cultural relations between civilised peoples in view of what is to-day the supreme interest of European civilisation—the establishment of conditions of genuine and enduring peace and goodwill between the nations. Universities are concerned with these relations, first as subjects of study and research, and secondly as responsive to influences which the universities can and do exert on them. It is mainly the latter aspect with which we are at present concerned, but limitations of space prevent more than a passing reference to the influence of vacation courses for foreigners.

Year by year visitors from nearly every civilised nation come to study in British universities. Since 1920 a census has been taken annually in October of students from other countries in the universities and university colleges of Great Britain and Ireland, and it has been ascertained that their total number at that season of the year is between four and five thousand. It has varied but little from year to year. Most of them come at an age at which, whatever its prejudices, the mind is receptive to new impressions. They come eager to learn, many of them hold scholarships awarded on the ground of exceptional capacity for learning, and many assume, after they have returned, leading positions in politics, administration, education, commerce, and industry in their own countries. The character of the impressions they receive is, therefore, a matter of no small importance. A very telling phrase, indicative of the importance of such impressions, was used by a professor of Harvard medical school when, speaking as exchange professor at Berlin in 1912, he described how, owing to his studying in a German university, he had become an "intellectual subject of Germany."

The universities of Great Britain and Ireland receive also from time to time university teachers from other countries. Such visits are generally for the purpose of delivering one or two lectures, and accordingly brief. In the few cases in which they extend over a whole term and the visitor has opportunities of entering fully into the life of the university, as in recent exchanges between

[1] *The Educational Record* (Quarterly Journal of the American Council on Education, Washington, D.C.), January 1925,—article on International Relations, by Dr. D. A. Robertson. "Syllabus on International Relations," by Dr. P. T. Moon (The Macmillan Co., 1925, pp 276), issued by the Institute of International Education, and to be followed shortly by a companion volume designed to appeal to the general reader as well as the college student. *Documents concernant l'expansion scientifique et universitaire de la France* (Paris, Les Presses Universitaires de France, 1923).

Bâle and Cambridge, Bâle and Manchester, Cape Town and Liverpool, and Harvard and Oxford, they are capable of contributing substantially towards the promotion of good feeling between the countries which they represent.

The number of British students who resort to foreign universities for study and research has not been ascertained Apart from attendance at summer vacation courses in language and literature, it is probably not large. During the past few years, however, a rapidly increasing flow of British students to the United States has been created by the institution of a number of fellowships and scholarships, notably those of the Commonwealth Fund, and the Laura Spelman Rockefeller, the Frances Riggs, the H P. Davison, the Jane Eliza Procter, and the Clarence Graff foundations. When these are in full operation they will maintain some seventy British students in American universities

During the War we were roused to a perception of the importance of fostering cultural relations with other countries. For a time "propaganda" was a word to conjure with, and the things for which it then stood were given a recognised place in our defensive armoury. Plans were worked out in detail for establishing a book distribution depot and a number of institutes in Continental countries, for encouraging the study of the English language and literature. These plans were about to be put into execution when the War came to an end, and, in the general retrenchment of establishments which ensued, they were hastily abandoned as being superfluous in time of peace With the single exception of the British Institute at Florence, which is entirely independent of Government support, we have no establishments in European countries charged with the duty of diffusing knowledge of British civilisation.

Another war-time plan with similar objectives was devised by Lord Balfour in consultation with the universities of the United Kingdom in May 1918. This plan, for sending a Universities Mission to the United States, did not depend on the creation of any official machinery and was forthwith carried into effect. The missionaries sowed their seed and left it to thrive or perish as might be, bringing back with them a great store of knowledge of American universities, in the acquisition of which they had established many friendly personal relations. The precedent thus set was followed by missions, similar but on a smaller scale, to France and to Belgium in 1919, and a conference of British and Swiss universities at Bâle in 1922.

Although it was no part of the plan for the Mission to the United States to create any permanent organisation, Lord Balfour took the opportunity of pressing upon the universities the desirability of an "organ of expression" which should, among its other functions, represent them in their relations with the universities of other nations. The suggestion bore fruit in the constitution of a standing committee of the executive heads of the universities of Great Britain and Ireland, the existence of which facilitated the organisation of the later missions.

As a result of discussions arising out of the report of the Mission to the United States, a committee of the Universities Bureau was formed for the purpose of promoting interchange between teachers and students of the home universities and those of the universities of the United States and also of other parts of the world. With no funds at its disposal, and no prospect of obtaining any to meet the expenses incidental to such interchanges, the committee could not be expected to achieve much: nor, in fact, did it.

In matters of this kind, countries with autonomous universities are at a disadvantage compared with those in which the universities are controlled by the State, as in France and Italy. In March 1919 the Ministers of Public Instruction of these two countries concluded an agreement for the organisation of exchanges of professors and students "afin de rendre les relations intellectuelles des deux pays plus étroites et de mieux faire connaître de part et d'autre leur développement littéraire, scientifique et pédagogique." Later in the same year, agreements with the Ministers of Public Instruction in Rumania and Jugo-Slavia provided for seconding French professors for service in those countries. Agreements made by the French ministry in 1921–1923 with Belgium, Luxembourg, Poland, and Czecho-Slovakia provided not only for systematic interchange of professors and students and reciprocal recognition of studies, diplomas, and professional service, but also for the setting up of permanent advisory commissions to ensure constant consultation and collaboration in the domains of scientific, literary, artistic, and pedagogic activity. Grants of money amounting to several millions of francs were obtained from the French treasury for bursaries and for remission of fees to enable foreign students to study in France

It has been pointed out already that as soon as the War was over, the plans made for establishing British institutes in foreign countries were abandoned, on the ground that their expense was no longer justifiable. In France other counsels prevailed, a higher value being placed on such services. The Ministry of Foreign Affairs, through its Service des Œuvres françaises à l'étranger, and the Ministry of Public Instruction, through its Service de l'expansion universitaire et scientifique, have co-operated with professors and other savants, university councils, comités de patronage d'étudiants, and various associations, in a strenuous and sustained effort to make French culture appreciated by foreigners, an effort financed largely by the State.

Branches of the Office National des Universités et Écoles Françaises have been established in London and New York; the Instituts Français at London, Florence, and Madrid have been maintained, and new institutes opened at Naples, Barcelona, Prague, Warsaw, Sofia, and Buenos Aires; a university mission with 24 professors of lycées and eight professors or lecturers in universities has been established in Rumania.

These establishments have greatly facilitated the interchange of students in various ways. At Prague, for example, the Institute conducted special elementary courses in the French language which enabled lawyers, doctors, engineers, artists, and scientific workers to qualify for French government bursaries. The New York director of the Office National reported in November 1922 that he had placed in the universities, colleges, and schools of the United States as professors of French 115 former bursary holders. During the previous year the number of French bursary holders in American institutions was 62 and the number of American bursary holders in France 60, while 116 students were recruited by the Office for study and travel in France. In 1922 there were 1392 Americans studying at French institutions as compared with 407 at British. The total number of foreign students in French universities that year, excluding vacation courses, was about 6000.

(*To be continued.*)

Looking into Things.

Concerning the Nature of Things. Six Lectures delivered at the Royal Institution. By Sir William Bragg. Pp xi+232+32 plates. (London: G Bell and Sons, Ltd., 1925.) 7*s* 6*d*. net.

TO deal with the "nature of things" as seen by modern physics in a course of six lectures to a juvenile audience is indeed a formidable task, and there are probably few besides Sir William Bragg who could have attempted it with any prospect of success. That success was achieved by the lectures there can be no manner of doubt to any one who had the good fortune to be present. The personal charm of manner of the lecturer and the beauty of his experimental illustrations was a great help, and no doubt many of his audience were carried smoothly along on the stream of his argument, in spite of the fact that the real inwardness of much of it must have been beyond their immediate understanding. The lectures cannot have failed to stimulate a vital curiosity as to the nature of things in some of the young hearers, and may perhaps have laid the foundation of more than one future career to be devoted to the successful deeper delving into that very "nature."

These same lectures, presented in the form of a book, are, however, a much more difficult matter. Cold print has to take the place of the living word, and illustrations, however well done, and descriptions, however clear, can never produce the same effect as actual experiment. To those who have heard the lectures the book must be most welcome as a permanent record in which they can study at greater leisure the facts and ideas put before them. To those reading the book by itself, however, we fear that its contents may prove a little difficult from the "juvenile" point of view. It is, of course, amazing to an older generation how much the more advanced juveniles of to-day are able to assimilate and understand, and possibly to a young mind coming fresh to such a field of ideas there may be less difficulty in following and adopting the writer's line of thought than to an older mind already burdened with many conceptions and some misconceptions. None the less, if one compares the book with the records of similar lectures by Tyndall or Faraday—and it fully deserves such a comparison—it seems to imply a much greater degree of scientific pre-education. To the more mature reader, on the other hand, it offers a delightful presentation of one of the latest developments of physical science in a most agreeable form The scientific investigator who possesses the somewhat rare gift of lucid and attractive exposition owes a duty to the world to use that gift in order to open up the new fields of discovery to a wider circle, and that duty is beautifully performed in this book.

Broadly speaking, the book deals with the atoms and the ways in which they are arranged or grouped in gases, liquids, and solids. The first chapter deals with the structure and size of the atom, full use being made of the knowledge gained from radio-activity and the ionisation-track method of Wilson The author takes care to state that the atom cannot be regarded as a hard sphere and describes its "astronomical" construction; afterwards, however, he follows the path of least resistance and speaks and evidently thinks of atoms in terms of spheres having definite sizes—a fiction which, though convenient, is apt to prove very misleading in detail. In the second chapter the nature of gases is discussed, with the aid of many beautiful experiments and analogies, while the third deals with the nature of liquids.

In the remaining three chapters the author comes to his own proper field of research, dealing with the nature of crystals, beginning with the diamond, studying ice and snow, and ending with the metals. Incidentally, however, many other things are touched upon, among them the simpler aspects of the author's own work on the measurement of organic molecules by means of X-rays, which is undoubtedly one of the

most remarkable achievements of that new weapon of physical research. It is not so very long since we still regarded the atom and the molecule as more or less theoretical conceptions the real size and weight of which could only be guessed at roughly. Here we see not only the dimensions and weights of the atoms accurately known, but also their exact arrangement in well-defined crystals as well as in thin layers of complex organic substances such as fats and waxes The plane diagrams of stereo-chemistry are confirmed and supplemented until we have true three-dimensional models.

Perhaps the only ground for real criticism of Sir William Bragg's book relates to his treatment of the subject of metals and alloys; that particular chapter contains several perhaps minor but unfortunate errors, such as the statement that the addition of nickel to copper does not affect the lattice of copper and does not cause hardening, or that the path of fracture in gold is between the crystals at ordinary temperatures and across them at high temperatures, whereas in reality gold—and all pure metals—normally break across the crystals at all temperatures except within a few degrees of their melting point. A most interesting account is given of the behaviour of crystalline metals under plastic strain, but the reader is left to infer that this was discovered by X-ray methods, whereas it was discovered so long ago as 1899, and there is the further doubt whether it is justifiable to conclude that because X-ray reflections from a thin film of gold show reflections coming from regularly oriented crystals, the film of gold must be entirely or even mainly crystalline. When, however, an author undertakes to deal with "the nature of things" in general, we cannot blame him if he does not prove himself omniscient. The pleasure and profit of the reader—whether juvenile or not—of this book will scarcely be diminished by these things. These readers, and we hope there will be many of them, will share with the scientific world generally a sense of gratitude to Sir William Bragg for having, in this book, done good service in helping to spread the light on "things in general" as physical science now sees them.

British Earthquakes.

A History of British Earthquakes. By Dr. Charles Davison. Pp xviii + 416. (Cambridge: At the University Press, 1924.) 25*s.* net.

FOR thirty-five years past Dr. C. Davison has made the subject of British earthquakes his own; he has written numerous studies of individual shocks and groups of shocks, and has now collected these, with much additional matter, into a volume which will always be of value to those who are interested in the phenomena which used to be called earthquakes, and will continue to be regarded as such by most of us, though the word has acquired a new meaning in modern seismology. By whatever name they may be called, they are a legitimate subject of study, and in this study Great Britain has taken a prominent place, in spite of the limited opportunities of observation; yet these opportunities are not so scanty as is often assumed, for Dr Davison enumerates 1175 distinct shocks, of which he has found record, up to the end of 1912, nor are they by any means all feeble ones; in 1185 the "great church of Lincolne was rent from the top downwards," and in the Colchester earthquake of 1884, 1245 buildings of various kinds were damaged.

If any fault were to be found with the work, it is that the interpretation of the facts is, throughout, presented in terms of one particular theory of origin. This is openly acknowledged by the author at the outset, where he states that the methods of investigation made use of are based on the theory that earthquakes are the result of successive steps in the growth of faults. It is always unfortunate when a worker limits himself to one theory; theories, even the most strongly established, are ephemeral, and when their time is come, they pass away into the limbo of oblivion; or, to vary the metaphor, they are tools which the workman must use, but should always be ready to discard when they are no longer the best adapted for the job in hand. In some instances the facts seem to be as readily, if not more easily, explicable by a very different theory from that adopted by Dr. Davison, yet it must be acknowledged that, if he has allowed the theory to colour his interpretation, he has not let it distort his presentation of the facts, and some of these are curious. It is not commonly known that the first recorded observation of rotation, without overturning, of objects, was made in London itself, where two china figures in a cabinet, in Bloomsbury, facing westwards before the earthquake of March 19, 1750, were found turned round to north-east, after the shock had passed. In 1816 the octagonal spire of the county jail at Inverness was broken through at about five feet from the top, and the upper part twisted round so that the angles of the octagon stood nearly over the middle of the sides below. These are instances of vorticose shocks, first brought into prominent notice by the report on the Calabrian earthquake of 1783, observed in nearly every great earthquake since then, and for long a subject of controversy.

The most noteworthy impression produced by an examination of the book is that British earthquakes are characterised by the magnitude of the area over which the disturbance was sensible As in all earthquake catalogues, there are a large number of shocks which only affected areas of a few miles across,

but of the larger ones, in nearly every case, the extent of the disturbed area is markedly greater than is usual, in countries where earthquakes are frequent. To take the case of shocks which attained a maximum intensity of viii° of the Rossi-Forel scale, Dr. Davison enumerates 8 excluding those of early date and imperfect information; of these, in only one case was the disturbed area distinctly less than 50 miles across; the other 7 affected areas of more than 200 and up to nearly 400 miles in diameter. In the case of Italian earthquakes, attaining the same degree of maximum intensity, barely 1 in 20 would affect an area of 200 miles in diameter, and 9 would be limited to less than 50 miles across, the other 10 reaching limits between 50 and 200 miles. No method has yet been published which, in practice, enables the depth of origin to be determined with certainty, but the difference between Britain and Italy, in the extent of country affected by earthquakes of the same degree of maximum violence, shows that the origins of the British earthquakes are, on the average, markedly more deep-seated than those of the Italian

Many other interesting observations recorded in the volume, which might easily escape notice in a work of its kind, are easy to find, as it is provided with an unusually detailed index. R. D. O.

Psycho-Analysis applied to Children.

Love in Children and its Aberrations: a Book for Parents and Teachers. By Oskar Pfister. Translated from the German by Eden and Cedar Paul. Pp. 576. (London: George Allen and Unwin, Ltd.; New York: Dodd, Mead and Co., 1924.) 24*s*. net.

IN his preface, Pfister, who is a Protestant pastor in Zurich, notes the difficulties inherent in the exposition of the analytical method to the ordinary reader, difficulties caused by the absence of generally accepted data and by the fact that the details of a single analysis would fill a volume. He claims that his vocation and studies have brought to his notice hundreds of mentally tormented persons in whom aberrations of the emotional life in childhood underlay the torment. Yet scientific psychologists have scandalously neglected this important topic, and "when a new and unfamiliar phenomenon like the activity of the unconscious makes its appearance they take to their heels—at least such has been the behaviour of most of the German psychologists."

After a survey of the handling of the problem by philosophers of different epochs, Pfister plunges into a psycho-analytical study of the manifold aspects of love aberrations in children. Freely illustrated by actual examples, this study shows Pfister as able to enter easily into an emotional *rapport* with his subjects, a *rapport* which undoubtedly aids him in obtaining their confidence and co-operation. His accounts of analyses are simply given, and in some cases it is possible clearly to distinguish between the associations of the analysand and the deductions of the analyst—a most important matter for the critical reader. Unless the reader dismisses these accounts as fantastic, they should carry conviction as to the reality of the mental processes concerned in the production of psycho-neurotic symptoms, the variety of which may surprise those unfamiliar with their ramifications: stammering, kleptomania, incontinence of urine, obsessive phantasies, inability to learn a particular subject or to settle down to a career, are a few of the problems that Pfister finds amenable to analytical treatment. Much of the book is devoted to individual cases, which serve to illustrate theoretical principles as they are developed, and the general application of these principles is summed up in the last six chapters, which are easily the most important and most interesting in the book.

Pfister is emphatic in declaring that in every school class there is a notable proportion of children with grave troubles and inhibitions, and that their teachers are in general quite ignorant of how to deal with them. Chapter xxvii contains common-sense advice as to methods of handling such children, short of analysis, which should help teachers or parents who realise the need for help, but one fears that those who most need it will repudiate the need The direct application of psycho-analysis to the individual is considered in the next chapter, where Pfister gives what is certainly one of the best popular accounts of psycho-analysis with its aims, difficulties, and limitations. Like most people familiar with unconscious processes, he realises the futility and even danger of "suggestion" when applied without knowledge, but he admits its applicability in certain instances. He shows how Dubois, the chief exponent of methods of persuasion, uses the emotional relationship of patient and physician as a means of alleviating symptoms even when he claims to work upon the intellectual plane "Auto-suggestion" the author compares with asking a man to lift himself up by his own boot-straps.

There is a tendency to diffuseness and exhortation that may repel some readers, and the translators occasionally betray a lack of acquaintance with English idiom. Perhaps the author goes beyond the popular conception of "love" in making it the basis of the reaction of the individual to his human environment; but many difficulties of the nervous person of any age lie in the inability to come into satisfactory

emotional contact with his fellows, and it is possibly true that the emotion concerned is inseparable from that of love. The book is obviously written by a worker who relies upon his own experience for his deductions; it should be widely read. M. C.

A Mystic Poetess of Ancient Kashmir.

The Word of Lallâ the Prophetess: being the Sayings of Lal Ded or Lal Diddî of Kashmîr (Granny Lal), known also as Lalêshwarî, Lallâ Yôgîshwâri and Lâlîshrî, between 1300 and 1400 A.D. Done into English Verse from the Lallâ-vâkyâni or Lal-Wakhi, and annotated by Sir Richard Carnac Temple Pp. xiv+292. (Cambridge: At the University Press, 1924.) 16*s.* net.

KASHMIR, as the author of this erudite work remarks in his introduction, is the home of wise saws and proverbial sayings; and of the latter none are held in higher repute than the Lallâ-vâkyâni, the "Sayings of Lalla," mainly because those sayings, couched in the form of hymns or lyrics, illustrate the Shaiva Yoga form of the Hindu religion on its popular side, and depict by the medium of metaphor and simile drawn from everyday life the actual hopes and fears of the common folk who nominally followed that system of religion and philosophy. Lalla herself, or Lal Ded as she is commonly called, lived in the fourteenth century of the Christian era, and appears to have spent much of her life in wandering about in a nude state, dancing and singing ecstatically. She was, as her verses indicate, a *yôgini* or female exponent of the Yoga discipline associated with the worship of Shiva, one of the two great gods of neo-Brahmanic Hinduism: but while expressing in her life and poems the utmost devotion to this aspect of the Hindu religion, she was influenced to no small extent, as Sir Richard Temple points out, by the ideas and teaching of the Muhammadan saints of Kashmir, chief among whom was Sayyid 'Alî Hamadânî, leader of the Nakshbandî Order of Sûffis. Though no authentic manuscripts of Lalla's poems now exist, the veteran scholar, Sir George Grierson, has succeeded in collating a tolerably complete text of her verses, which were originally composed in a now obsolete form of Kashmiri and were handed down orally from generation to generation, and it is this text which Sir Richard Temple has translated into English verse.

Apart from the actual songs and their rendering, this book is valuable by reason of the admirable survey of the sources of Lalla's religion and of the theory and doctrine of her faith, which the author has prefixed to his interpretation of her hymns. To those who desire a succinct and illuminating exposition of the growth and nature of the extraordinary medley of magic and metaphysics which we know as Hinduism, Part I. of this work can be confidently recommended, written as it is by one who has steeped himself for fifty years in the history, the antiquities, and the lore of India. Commencing with the Aryan religious instinct, which has a distinctly theistic trend in contrast with the atheistic tendencies of those Asiatic peoples who dwell farther to the East, the author expounds the gradual growth of the Aryan religion and of the old Brahmanic doctrines, which were a blend of "especially developed aboriginal ideas deriving from lands North and West of India with those of aboriginal India itself." He shows how the belief in sacred syllables, *mantras*, and riddles arose, comments lucidly upon the *Upanishads* and the Brahmanic schools of philosophy, and then describes the origin and nature of Buddhism, Jainism, and the Bhâgavat religion, with its great doctrine of *bhakti* or devotion to a personal God, and how the latter joined forces with Brahmanism in its struggle against the atheistic creed of the Buddhist, and so led directly to the identification of the Brahmanic Vishnu with the sole God, Bhagavân. It is observed that Sir Richard Temple dates the death of Buddha "with sufficient certainty" in 488 B.C. There is evidence, no doubt, to support this date; but it is by no means improbable that the date accepted in Ceylon, namely 543 B.C., is correct, particularly as this fits in with the chronology disclosed in the important Hatigumpha inscription of Khâravela, which at quite a recent date has been subjected to close scrutiny by two leading Indian scholars

In one respect the author's estimate of the influence of Alexander's invasion upon India seems also open to comment. He attributes to the Macedonian conqueror "the teaching of state-craft on a large scale and generalship to the Indian Chiefs." Such Hellenistic elements as can be detected in Indian civilisation were certainly due indirectly to the invasion, but Indian polity and the caste-basis of society remained substantially unchanged, and even in military science Indians showed no disposition to learn the lessons taught by Alexander. The kings of India preferred to go on as before, trusting to their elephants and chariots, supported by hosts of inferior infantry. It was not until the sixteenth century that any leader appeared to repeat with success the shock tactics of the Macedonian cavalry. The date of the Kushân king, Kanishka, accepted by Sir Richard Temple, is likewise questionable, and it seems reasonable now to place that king's accession in the early years of the second century A.D. These, however, are minor criticisms and in no way detract from the value of the author's survey of the influences which moulded Lalla's religious belief. His account of the gradual permeation

of Hinduism by the Tantric doctrines and the often revolting worship of the *Shakti* or Female Energy, of the influence of Southern Indian Vaishnavism and of the great Hindu revival associated with the genius of Shankarâchârya, and lastly of Islam upon the minds of Lalla's age, is fully in keeping with the remainder of his careful explanatory essay, and must be read by those who desire to follow the author's detailed exposition of the Trika philosophy, which Lalla conveyed to the public in the guise of popular hymns.

As to the actual translation of the hymns, Sir Richard Temple has wisely refrained from adhering slavishly to the literal rendering of Lalla's words, but has endeavoured to convey her meaning in English metrical form, which, so far as possible, is modelled on the roughness and irregularity of the original. In order that the reader may lack no aid to understanding the inspired words of the prophetess, he has prefixed to each hymn or poem a brief and complete explanation of its inner meaning. Sir Richard Temple's work, which is printed and produced in a style worthy of the Cambridge University Press, is a valuable addition to the growing library of books dealing with the religious literature of India. Our Bookshelf.

Humanism and Technology and other Essays. By Principal C. Grant Robertson, Sir Thomas H. Holland, Prof. C. H. Desch, Sir Henry Fowler, Prof. F. W. Burstall, Prof. W. Cramp. Pp. 91. (London: Oxford University Press, 1924.) 3*s.* 6*d.* net.

THIS is a brilliant little book and as useful as it is brilliant. The title scarcely does it justice, for the book contains essays dealing with the relations of humanism and science generally and a great deal of admirable good sense on education. The occasion of their composition was a vacation school for engineering teachers held in the University of Birmingham and in Oriel College, Oxford, in the summer of 1923. Mr. Grant Robertson, the Principal of the University of Birmingham, fitly leads off with the most general paper and one of the best things in the book, on "Humanism and Science." The note which he strikes is sustained throughout the volume; both sides of education are needed for the adequate training even of the pure technician. If "humanism" means knowledge of the best that has been thought and felt, how can you omit from the best the finest achievements of the scientific intellect? Conversely, students of science who are to make the best use of their training should have at least such contact with the humanities as is implied in an acquaintance with general history, and in particular with the growth of science in relation to the evolution of human society.

Sir Thomas Holland has a humorous epigram on this point, which must not be pressed too far. "It is not," he says, "separate courses of history and science—a mechanical mixture—that are wanted, but the history of science itself, that is, a chemical compound. Giving two separate doses of two unrelated subjects to act as mutual correctives is equivalent to giving a man a metallic sodium pill with a sniff of chlorine gas, when what he wants is merely a pinch of common salt." Sir Thomas Holland lays great and well-deserved stress on the value of biography in historical teaching, and would like to try the experiment of covering a syllabus of chemistry or metallurgy by lectures on biography alone. Prof. Burstall is still more definite. He points out that physical science, as we know it, is a product of the last two hundred years, and its practical applications of the last century and a half. Hence he would have the student consider the historical aspect of the development of engineering since 1775, the starting-point of James Watt's work.

This would no doubt be excellent for the engineering student during his special training; but we should like to put in a plea for the earlier history of science as a part of his general education before he begins to specialise. F. S. M.

The Properties and Uses of Wood. Prepared in the Extension Division of the University of Wisconsin by Arthur Koehler. (University of Wisconsin Extension Texts: Industrial Education Series.) Pp. xiv+354. (London: McGraw-Hill Publishing Co., Ltd., 1924.) 17*s.* 6*d.* net.

THE author of this book is one of the chief workers in the Forests Products Laboratory at Madison in Wisconsin, which was established by the United States Forest Service in 1910. This laboratory is the largest and best equipped of its kind in the world, and during the fourteen years of its existence has accumulated a large mass of data concerning wood. The work is distributed amongst seven sections—timber mechanics, timber physics, wood preservatives, pulp and paper, derived products (turpentine, tar, charcoal, etc.), industrial investigation, and pathology The results of the researches at Madison have already led in the United States to closer use of timber, to better manufacturing methods, and to prolongation of the life of wood in service. The enormous saving of material due to new methods will, it is believed, postpone the advent of the timber famine, which seemed a few years ago to be so near at hand.

We are fortunate, then, to have this elementary textbook produced at Madison, as it brings to our notice in a handy volume the more important facts about the properties of wood, and shows us how these properties affect the utilisation of timber. The chapters deal consecutively with the sections outlined above; and a detailed notice of the subjects treated is unnecessary. We may, however, signal some points of interest. The great drawback to the use of wood is its tendency to shrink and swell, from which result warping, checking, case-hardening, and honeycombing in timber, as is clearly shown in the third chapter. The practical devices against these defects are seen in aeroplane propellers, where the wood used retains its shape, although it is subjected to the most varying conditions of atmospheric moisture and temperature. The chapters on modern methods of testing timbers are well done. The U.S. Forest Service recommends, after many tests, the classification of each species of wood into four grades, according to the defects they

contain, and assigns definite working stresses for each grade, as shown in Table xv. of this book.

Air seasoning and kiln drying are dealt with in two chapters. The latter process is becoming more and more employed; and when done properly it shortens the time required and turns out a better product than ordinary air drying. We recommend this book to foresters and to all interested in improved methods of utilising timber and eliminating waste.

Ethnographie von Makedonien. Geschichtlich-nationaler, sprachlich-statischer Teil. Mit einem Trachtenbild. Von Prof Dr. Gustav Weigand. Pp. iv + 104. (Leipzig. Brandstetter, 1924.) 3 marks.

PROF WEIGAND is well qualified for his task, and has written an extremely interesting work. He brings out one theory which will be novel to most readers, that the Albanians are not the descendants of the ancient Illyrians, but of the Bessi, a tribe of Thracians referred to by several chroniclers He considers the former a maritime people, whose centre was in the north and west of the Balkans, where they may be traced in the Morlacchi of Zara Cici of Istria, where the Latin speech still lingers on, and Venetians, all of whom are connected with the authors of the Messapian inscriptions of southern Italy. He thus makes Albanian the modern representative of the old Thracian language, which occupied a position intermediate between the Slavonic and Iranian groups He considers that the ancient Thracians became thoroughly Romanised, and, with the exception of the Bessi, forgot their tongue; the fact that Bulgarian, Rumanian, and Albanian, although in no way related, all have a postfixed definite article, unknown in any other Latin or Slavonic tongue, he attributes to the influence of the old Thracian language, and adduces a whole series of analogous occurrences; numerous names of places and of plants are explained as survivors of the old tongue As an example, we may quote Plovdiv as a Bulgarian corruption of the Thracian Pulpidava.

When dealing with the relations between the Bulgarian, Macedonian, and Serbian languages we feel that the learned author has been influenced, in spite of his disclaimers, by his political sympathies. When, for example, on p 73 he gives a list of Macedonian words which he states are *never* used in Serbian, he is certainly influenced by his greater familiarity with Bulgarian · all the words he quotes may be heard commonly in Yugoslavia, even in the north and west.

Electrical Design of Overhead Power Transmission Lines. a Systematic Treatment of Technical and Commercial Factors; with Special Reference to Pressures up to 60,000 Volts, and Distances up to 100 Miles. By William T. Taylor and R E Neale. Pp vii + 266. (London. Chapman and Hall, Ltd., 1924.) 21*s.* net.

THE transmission of electric power in bulk over considerable distances has brought into prominence many almost purely mathematical and physical problems, the solution of which is necessary for economical design. Except in the case of abnormal working, the transmission lines are not traversed by high frequency currents or "surges" of electrical energy It is necessary, however, to know how the resistance and inductance are affected in these cases, and there is a demand, therefore, for mathematical knowledge to simplify and evaluate the requisite formulæ. Considerations of economy also make it necessary to use a very high voltage. But at very high voltages the lines are surrounded with brush discharges which engineers dignify by the name of the "corona" effect. It is essential to know at what pressures these effects begin, and also the power expended in maintaining a corona on transmission lines It is therefore necessary to know the physics of the phenomenon.

The authors have limited the scope of this volume to the consideration of lines up to 100 miles in length and to working pressures not exceeding 60,000 volts. The introduction of hyperbolic trigonometry is therefore rendered unnecessary As power systems in Great Britain are included within these limits, at least at present, this book will prove of use in practice. The authors have wisely adopted international notation, and have laid stress on the standards adopted by the British Engineering Standards Association They give references to practically all the useful literature of the subject

Air Ministry: Meteorological Office British Meteorological and Magnetic Year Book, 1916. Part 5: *Réseau Mondial, 1916. Monthly and Annual Summaries of Pressure, Temperature and Precipitation at Land Stations, generally Two for each Ten-degree Square of Latitude and Longitude* (M O No. 227g, Tables) Pp. xiii + 115. (London: H.M Stationery Office, 1924.) 22*s.* 6*d.* net

THESE results are now available for seven consecutive years, 1910–1916, and with the publication of each additional year the data are becoming of increased value for meteorological and physical inquiries. All the information refers to land stations, no data over the sea being as yet directly obtainable. Observations are given for 440 stations, and most of these are under the control of government meteorological services. The results show that the highest mean pressure for the year, at mean sea-level, is 30·19 in. at Barnaoul and Minousinsk in 53°-54° N 83°-93° E., the lowest mean pressure 29·45 in is at S Georgia in 54° S 37° W. The highest mean temperature was 85°·5 F. at Berbera, Somaliland, in 10° N. 45° E., the lowest 10°·6 F. at Markovo-sur-Anadyr in 65° N 171° E The largest rainfall for the year was 486 inches at Cherrapunji in 25° N 92° E., which is 76·3 in. more than the average, followed by 269 inches at Akyab, 77·6 in. more than the average. No rain was measured during the year at Puerto de Arica or at Iquique, at both of which stations the average annual fall is 1 mm. The only rain expected at Puerto de Arica is 0·04 in. on the average in January, and at Iquique 0·04 in. in July. Notes are given for each month on the state of the ice in the Arctic Seas and in the North Atlantic.

Historical Atlas of the British Empire. Pp. 20. (London: Macmillan and Co., Ltd., 1924.) 1*s.*

A USEFUL cheap atlas with thirty-nine black and white maps of the British Empire. Most are only in outline, but a few show orographical features. The text consists solely of a chronological list of events bearing on the history of the British Empire from 55 B.C. to the present day. A great many facts have been crowded into twenty pages, but the maps are the best part of the book.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Hydrography of the *Dana* Expedition.

IT may interest readers of NATURE to know the results of some of the hydrographical investigations carried out by the Danish *Dana* Expedition, under Dr Johs. Schmidt, in the Atlantic in 1921–22

These investigations were begun in the autumn of

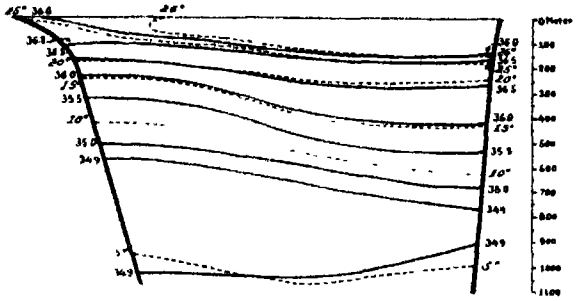

FIG 1 [1]– Vertical section from Cape Yucatan to Cuba The dotted curves are isotherms, and the unbroken curves, isohalines

1921 from the Straits of Gibraltar via Madeira and the Cape Verde Islands to the north-east coast of Brazil, they are of great interest on account of their bearing upon the circulation in the Atlantic

In the eastern part of the Atlantic, outflowing water from the Mediterranean was found as a characteristic stratum with relatively high temperature, and a salinity maximum at about 1000 to 1200 m, so far south as the Cape Verde Islands (see NATURE, January 12, 1922), in the western Atlantic, on the other hand, a colder water layer was found at a depth of 700-1000 m., with a minimum salinity, showing, indeed, values so low as 34·6 per mille, a stratum originating in the southern part of the Atlantic, and then forcing its way up into the western portion of the north Atlantic

The section in question intersects the equatorial

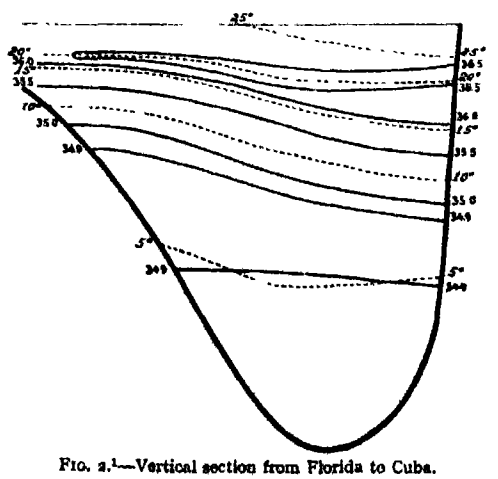

FIG. 2.[1]—Vertical section from Florida to Cuba.

current, which exhibits highly varying salinity at the surface (34-36 per mille); the temperature is high, but decreases rapidly with increasing depth, falling to 10° at a depth of 200-300 m.

[1] All the diagrams are drawn to the same scale.

Part of the equatorial current, with the subjacent south Atlantic water layer, flows into the Caribbean Sea, but the two are here separated by a stratum with high salinity (more than 36·5 per mille) from the Sargasso Sea, which edges in between them at a depth of about 200 m

These three water layers of different origin flow through the Strait of Yucatan into the Gulf of Mexico, but, as is seen from the sections shown in Figs 1, 2, and 3, they turn off at once to the eastward along the north coast of Cuba, continuing between Florida and the Bahama Bank The deflexion due to the earth's rotation causes the isotherms and isohalines to incline to the eastward, the inclination is most pronounced in the Strait of Bemini between Florida and the Bahama Bank, showing that the current reaches its greatest velocity here

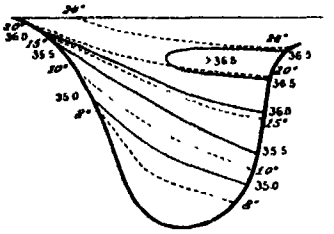

FIG 3 [1]—Vertical section from Florida to Bahama Bank

The south Atlantic substratum can still be discerned in the Strait of Bemini, but soon disappears altogether, whereas the two others, namely, the surface layer from the equatorial current and the salt intermediary layer from the Sargasso Sea, form the Gulf Stream or, more correctly, the Florida Current, which flows north-east along the east coast of the United States outside the coast shoal with a velocity probably varying considerably, like the breadth of the current itself, with the season A value frequently found for the breadth is 60 miles, and the rate of speed may amount to more than three miles an hour

In a section from Norfolk, Va, towards Bermuda (Fig. 4) the Florida current is sharply defined in the spring, but doubtless becomes somewhat effaced in the course of the summer In the waters south of Newfoundland, the Florida Current meets the Labrador Current, giving rise to a mixed product with somewhat lower temperature and salinity than are found in the continuation of the Antille Current which

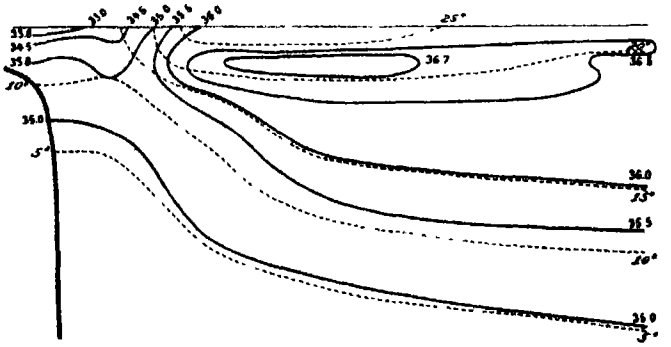

FIG. 4 [1]—Vertical section from Norfolk in a direction towards Bermuda

runs on the right side of the Florida Current and consists of water masses which keep outside the islands of the Antilles

Some of the cold water from the Labrador Current flows on toward the south-west, over the coast shoals, and is gradually warmed, but right to the southern

part of the coast shoal the polar origin of the water is still distinctly perceptible.

The mixed product arising from the Labrador and Florida Currents fills the considerable area of sea south of Iceland, while the warm and salt water washing the coasts of north-west Europe is undoubtedly mainly derived from the Antille Current The term "Gulf Stream" generally employed in European parlance to denote the warm current in the north-eastern part of the Atlantic, must therefore be regarded as inappropriate, since it can only rightly apply to the current off the east coast of the United States, and even this would be better designated by the older name of "Florida Current," as the current in question does not originate in the Gulf of Mexico, but comes from the equatorial region, and covers only the shortest possible distance in the Gulf of Mexico.

A detailed report of the results here summarised will be published in the Journal of the Royal Danish Geographical Society for 1925

Absolute Seismometry: a New Method.

THE fundamental problem in all seismometers is to find or devise some observable thing which shall not partake of the earthquake motion Such a thing is spoken of as a steady point, and the work of a seismograph is to record the position of the steady point relative to the neighbouring earth as a function of time. Unfortunately, most mechanical systems under our observation or control require terrestrial connexion through agencies which inevitably transmit forces, so that steady points are subject to acceleration when their connecting links are disturbed. That is to say, the steady point is steady until the arrival of the earthquake and not longer

"If one could only be suspended in space near the earth's surface," Hobbs observes, "but without any attachment to it, the problem of registering the earth's motions would be a simple matter. . . .

"The universal and unsatisfactory substitute for the theoretical unattached observation station outside the earth is the inertia of rest inherent in a suspended mass—the bob of a pendulum . . All pendulums have natural periods of vibration which are dependent on their length, and except in the most improved and elaborate instruments they inevitably combine the motions imparted to them by earth shocks with their inherent natural periods of vibration"

The difficulties are like those which a surveyor would encounter if obliged to survey the shore of a lake with only a row-boat as a place to set his transit. Nevertheless, pendulum seismographs in skilful hands give good results A Mohorovicic states that by exercise of great care the true local earth movements may be known from a seismogram with a mean error so small as 10 per cent. It is still of interest, however, to consider proposals which offer the possibility of an escape from the earth connexion.

It is stated that astronomers have frequently noted the sudden apparent displacement of stars which were under observation at times of earthquake, and that a seismometer utilising this effect has been proposed. Such an instrument would have the advantage of a truly steady point, but, passing over other objections, would have the limitation of sensitiveness only to rotations and not to translations of the earth particle.

The writer has considered using a freely falling body as "steady point" Such an object is not steady in any sense of being stationary, but it is quite detached from local earth features and will not participate in any changes of earth motion that may originate within the period of its fall. It would be better to speak of it as an "independent point."

If a body be allowed to fall from a support which has at the instant of release a horizontal speed V, then after the lapse of time T the body will have departed a distance VT from the vertical containing its point of release. If this departure is recorded by a mechanism which shares the motion of the support, then the recorded departure, X, is given by

$$X = VT - D, \quad . \quad . \quad . \quad (1)$$

where D is the displacement of the recording mechanism during the interval T. Expressing D otherwise, we may write

$$X = VT - \int_0^T V dt. \quad . \quad . \quad . \quad (2)$$

If a continuous succession of falling bodies be observed, X is a known, continuous function of time and equation (2) suffices to determine V completely.

Rather than a succession of discrete bodies a continuous liquid jet may well be employed, as has been done in the experiments to be described. A table free to move in one horizontal direction carried a reservoir from which a liquid ran out vertically in a jet which remained continuous for a length of more than three metres The lower end of the jet passed through a recording device wherein its shadow was cast through a horizontal slit upon vertically moving bromide paper. With the rate of motion of the paper known, the resulting trace gave a complete history of the excursions of the foot of the jet when a disturbance was imposed above.

In order to provide a correct record of the imposed disturbance (limited in this instance to linear horizontal oscillations) a metal pointer was arranged before the slit and mechanically coupled to the moving table so as to reproduce correctly its to-and-fro motions. The shadow of this pointer on the photographic paper left the desired record Appropriate time-signal shadows were also provided.

These experimental conditions differ from those required by equation (2) in that the recording mechanism does not now partake of the motion of the reservoir. The equation of the trace would now be

$$X = s + T\, ds/dt, \quad . \quad . \quad . \quad (3)$$

where s is the displacement of the reservoir orifice at the instant of the release of the particle which is to arrive at the recording mechanism with the horizontal displacement X. For any series of motions of the source of liquid, two curves should appear on the record, related to each other as are X and s in (3). The sample record presented in Fig. 1 confirms this expectation down to the limits of measurement. The broken trace at the top of the figure is a time-signal, being the shadow of a reed which was executing 10·06 complete vibrations per second. The sinuous line next below is the s curve. Next comes another time-signal, marking seconds, with the shadow of the jet at the bottom of the figure. The sequence of events is from left to right. The record covers a period of twenty-four seconds.

A time interval of something less than a second is to be noted between the initiation of the disturbance at the source and its appearance at the foot of the jet This interval is T, the time of fall. The slope of the s curve is, of course, ds/dt. Accordingly, if a line tangent to the s curve at any point be produced toward the right until it shall have progressed from the point of tangency a distance T in the direction of the time axis, the ordinate of its extremity should, according to (3), be X. It may be shown from the figure that such is the case.

It was not thought worth the additional trouble to perform a direct test of equation (2). It will be granted at once that a verification of (3) leaves no room to doubt the validity of (2).

Considered as a possible seismographic method, the device presents several interesting features Two components of motion of a jet are readily registered on one paper through the use of an inclined plane mirror. The apparatus is extremely insensitive to tilts Its response is to velocity rather than to displacement The amplitude of the trace may be increased not only by optional magnification but by obtaining a longer time of fall, thus actually increasing the relative movement of the observed mass and its surroundings As in pendulum instruments, we are dealing here with an inertia seismometer, but it is the inertia of motion rather than of rest which it is now proposed to employ.

When the motion of the source is quite rapid the trace does not obey equation (3), presumably because viscosity prevents the fall from being truly free. Viscosity operates at low speeds too, but without measurable effect on the trace The traces now in hand were made several months ago. It is thought that the liquid used was unnecessarily viscous (some 300 poises) and the jet unnecessarily coarse Further work is in progress.

FIG 1

The Positive Electrical Drift in the Air.

IF electrostatic measurements are made in the air on a bridge over the permanent way near any railway station, extraordinarily large positive charges given off by steam locomotives will be observed, especially on starting up. These positive charges are carried by the wind for long distances. Under favourable conditions, that is, when the sky was clear and free from interference from clouds, and a stiff steady wind prevailed, I have noticed strong charges down wind a mile away, from a single engine working in a country siding. Scarcely any effect is noticeable in the opposite direction. Similar results, although on a much smaller scale, are observed near steam-driven road engines. They are not noticeable near petrol-driven or electric traction. These charges are presumably similar to those employed in Sir W. Armstrong's hydroelectric machine.

Under any of the large spans covering the railway termini in London, the potential gradient is zero when they are unoccupied. When locomotives are present high potentials are observed.

On some of the bridges over the Thames very high potentials may be observed according to the direction of the wind with respect to railway traffic. At Blackfriars, for example, very strong positive charges are carried by east winds from trains passing to and from Ludgate Hill and neighbouring stations.

With a westerly wind the Cannon Street traffic affects London Bridge, and that on Hungerford Bridge can be felt on Westminster or Waterloo Bridges, according to circumstances.

Of the two factors concerned in atmospheric potentials, that is, "the forces of Nature" and the activities of man, the latter appears to me to predominate in the majority of the daily readings in and near the metropolis To what extent the former intervene can be deduced only from observations conducted many miles from the drift air from locomotives, steamers, road engines, and doubtless other forms of stationary engines. My own measurements point to the sun as the agent in this case.

The presence of these air-borne charges must necessarily affect the readings at Kew Observatory, surrounded as it is by a dozen stations within a radius of about two miles

Many readers of NATURE will possess copies of the Royal Society's Handbook of the scientific exhibits at Wembley In Dr Chree's admirable article there —a model of popular exposition — curves of the potential gradient at Kew are shown These curves, with their minima during the early hours of the morning, and their maxima at 8-10 A.M and 7-9 P.M, would almost stand for traffic intensity curves The gradient here at Upminster, 17 miles E N E of Charing Cross, when the sky is clear and the wind does not set from the local station, appears to depend principally on London drift air, being very strong with W. to S.W winds and very slight with easterly ones

In any case, the distribution and influence of these positive charges deserves the careful attention of meteorologists During hot weather they appear to be dispersed more rapidly than in cold, for a rising barometer and frost result in unusually high concentrations These drifting positive charges constitute electric currents—in some circumstances these might give rise to compass irregularities Their irregular distribution may conceivably be connected also with certain kinds of "atmospherics" in wireless

WILLIAM C REYNOLDS

"Whartedale," Upminster,
February 11

THE phenomena of electrification in connexion with steam, to which Dr W C Reynolds refers, are described by Mr W A Douglas Rudge in a paper read before the Cambridge Philosophical Society (Proc., vol. 18, p 127), and referred to in NATURE of November 18, 1915 (vol. 96, p 332). The breaking up of water, whether the act of man or of Nature (as in waterfalls), is a powerful source of electrification, but I am unable to accept Dr. Reynolds's suggestion that railway steam may account to any large extent for the early morning minimum and evening maximum of potential gradient recorded at Kew Observatory If this were the case, the change from steam to electric traction in the local trains should have had a profound influence, whereas the daily maximum and minimum

in question seem as marked now as thirty years ago. Richmond station, moreover, is ¾ mile from the Observatory, and is not in the direction from which the prevailing wind blows. It is not a station where much shunting is done A minimum in the morning and a maximum in the evening have been observed at most places, town and country alike.

Dr. Reynolds is, however, I think, quite correct in believing that electrical phenomena in and near large towns are much influenced by the works of man. Steam no doubt may play an important part in some localities, but atmospheric pollution by smoke is, I think, a much more important factor. Reasons for this belief will be found in the Royal Society Handbook to which Dr Reynolds refers.

Undoubtedly a continuous record of potential gradient and other electrical phenomena at some really country place, situated desirably to the south-west of London, is a somewhat urgent desideratum

C CHREE.

Experimental Study of the "Soaring" of Albatrosses.

A SERIES of experiments was made by me in Africa in 1920 in order to study the flight of the vulture Kites were brought into the immediate vicinity of the soaring birds, and carried with them sensitive apparatus, making it possible to find, by means of electrical connexions with registering apparatus on the ground, the variations of internal energy of the air (temperature within 0·02° C., pressure within 0·1 millimetre, speed, direction, and horizontality of wind variations)

The registrations so obtained showed that in all of the observed cases of flight, the birds used ascending air currents, the origin of which was almost always due to temperature variations, the ascending air columns often shifting according to the temperature variations The experiments enabled me to measure (by the relation of the horizontal and vertical speeds of the bird relative to the air) the lift/drag ratio of these birds, which is about eighteen [1]

The soaring of albatrosses and other sea-birds seemed to be quite different. The French Government accordingly sent me on a mission to the South Seas, in the neighbourhood of South Georgia, to study the flight of these birds Registering apparatus was made use of, either on board of the ship or at sea, by means of floaters left from the board (to avoid the possible perturbations due to the boat) The variations of the internal energy of the air were so studied, as in Africa, amongst birds Films taken by an automatic cinematographic apparatus, moved by clockwork, enabled me to find out, by photographic reconstruction, the trajectory of albatrosses and their velocity (The average speed, relatively to the air, was 22 metres)

The experiments showed that the soaring of albatrosses always takes place when there is no ascending current over the waves and the wind is even, but then it is always observed in the air strata where albatrosses fly, that the wind is *increasing according to the altitude*, doubtless it is the friction of the sea on the wind in the low strata that decreases its velocity [2] Albatrosses, then, are continually manœuvring up and down, turning from time to time, going up against the wind and going down with the wind, so that they alternately put themselves in strata of air of different speeds.

I took numerous measurements in the open sea in order to find out experimentally this variation in altitude of the wind speed that albatrosses use. These measures enabled me to calculate the energy gained by albatrosses

The results are as follows:

(1) This sort of soaring is possible only for very swift birds It needs a minimum wind of five metres, close to the water.

(2) The stronger the wind is, the higher (10-15 metres) the birds must do their upper turn

(3) These trajectories of albatrosses are the most advantageous as regards gain of energy

These theoretical conclusions are in agreement with the observations. Albatrosses consequently use the slackening of the wind speed due to friction on the surface of the sea P IDRAC.

Bio-Chemistry of Muscle Contraction.

THE films of long-chain organic compounds (*e.g.* the aliphatic mono- and dibasic acids) crystallised on glass surfaces possess a structure in which the molecules are orientated so that their terminal groups lie in a series of planes parallel to the surface on which they are deposited This structure is similar to that postulated by Friedel for liquid crystals (*e.g.* soap curds) in the smectic state In the lamellæ between the planes, the long chains are arranged with respect to the surface at an angle which depends on the nature of the terminal group For the mono-basic fatty acids the inclination is about 55° and for the esters of these acids approximately 90°.

Films of aliphatic organic acids when crystallised on glass or on the surface of aqueous alcoholic solutions have been examined by convergent polarised light and found to show the biaxial interference fringes typical of crystal sections in which the acute bisectrix is not normal to the surface. The two optic axes may be accounted for by assuming that successive molecules of acid lie in different directions in space giving rise to a chain of molecules running in a "zig-zag" manner from the surface of the glass. The angle between the chain directions of two adjacent molecules will depend on the configuration of the terminal groups, being different for an acid and its ester and salt.

This type of crystal structure has a possible significance in physiology, for if it be present on the surface of a muscle fibre it would provide a mechanism by which contraction on stimulation could occur

A striated muscle fibre shows alternate isotropic and anisotropic striæ along its length. On contraction, the width of the striæ decreases, the diameter of the fibre increases, and a tension is produced along the axis According to Engelmann, the active constituent in producing the contractibility is the anisotropic part of the muscle. The anisotropy is conceivably due to the presence of orientated molecules, presumably of long-chain amino-acids, which are either present in the membrane of the muscle fibre or are distributed in fibrillæ throughout. Assuming for the moment that the membrane is anisotropic due to the presence of long chains of salts or esters of amino acids, and that these are orientated so as to give a zig-zag arrangement of the molecules in a direction parallel to the axis of the fibre, and further consider the effect of converting these salts into amino-acids. In the first place, the

inclination of successive molecules to one another would be altered just as is the case in the crystalline state when an ester is converted into an acid, and, in the second place, the length of the zig-zag composed of a finite number of molecules would be shortened If the chains of the molecules commence at the interfaces between the isotropic and anisotropic regions, then the chemical change will produce a tension along the length of the fibre

When a contraction wave passes along a muscle fibre the hydrogen ion concentration in the muscle increases, due to the production of lactic acid from glycogen, so that the chemical changes occurring during stimulation are sufficient to account for the conversion of a salt into an acid and of an expanded into a contracted molecular film, and hence for the tension along a muscle fibre W E GARNER

Ether and the Metaphysical Mind.

DR JEANS states in his Kelvin Lecture to the Institution of Electrical Engineers, published as a Supplement to NATURE of March 7, that our own physicists have asked for a machine, while "the more metaphysical minds of the Continent have usually been content to accept action at a distance" He goes on to say "it is something more than a coincidence that Newton, Clerk-Maxwell, Kelvin, and Faraday are all British, while Boscovitch, Einstein, and Weyl are not"

Of the three men chosen as typical of the more metaphysical minds of the Continent, all are mathematicians primarily, while two at least of them are of eastern origin--Slavonic or Jewish These men are therefore representative—if genius is representative of anything—of eastern rather than western Continental thought Two natural philosophies are apparently now available—a natural philosophy based upon essentially British lines of thought as represented by Newton, Clerk-Maxwell, Kelvin and Faraday, and a natural philosophy based upon an eastern philosophical outlook Does this not perhaps account for the difficulty that relativists are finding in getting this new plant of eastern origin to take root in British soil? Dr Merz, in "A Fragment of the Human Mind," pp 18, 24, 25, etc, has pointed out more than once that when an *impasse* is reached in a discussion of some philosophical question, as, for example, in "Hume's dilemma," it is characteristically British to appeal to common sense

We appear to be witnessing not so much the birth of a new theory, for there are already half a dozen or more species of relativity theory — Einstein's, Eddington's, de Sitter's, Weyl's, Silberstein's, Whitehead's, Robb's, and so on—as the birth of a new branch of knowledge—*mathematical metaphysics*

Just as there have always been minds that prefer physics to metaphysics, so there will always be minds that prefer mathematical physics to mathematical metaphysics The former will draw their inspiration, meantime, from the Larmor-Thomson-Lodge School; the latter from the Einstein-Eddington-Jeans School The essential distinction between them appears to be that one demands "a machine," *i.e.*, a mechanical (not necessarily Newtonian) model of the physical universe, built in normal space and time; whereas the other is content with describing it through the medium of a mathematical analogue or map Many of us would be well enough pleased to possess either —the model or the map.

F. F P B.

The Migrations of the Painted Lady Butterfly.

ELSEWHERE in this issue (p 535) is a short account of our present, very incomplete knowledge of the migrations of the Painted Lady butterfly (*Pyrameis cardui*) This article has been written with the sole object of obtaining co-operation in a problem which can only be solved by the combined efforts of a number of observers who know what to look for and are kept interested by knowing what relation their observations bear to the whole question

As is stated in the article, only in Western Europe, North Africa, and Palestine is there any possibility of piecing together the hundred or so known records, and even in this area the conclusions will not be trustworthy until the records are ten times more numerous In the rest of the world, and particularly just to the south of the Palæarctic Desert belt, in Nigeria, Senegal, and the Sudan, for example, every record is of the greatest value, and any one may help to give the clue to the mystery of the origin of the flights which reach the North African coast

May I, therefore, ask any interested person in any part of the world to publish—or to send to me - notes on the seasonal abundance of *Vanessa cardui* in his district, and particularly on any sudden appearances or disappearances of large numbers, and in general any notes or observations relating to the migration of this or any other insect

Records of actual migrations should include the locality, date, species, approximate numbers, sexes (if possible), direction of the flight and of the wind, and any other notes on the meteorological or biological conditions If, in addition, specimens actually caught on migration could be sent to me for examination and dissection, I should be very much obliged

All original notes and observations sent direct to me will be published, as in the past, with full acknowledgments if of sufficient interest

The Spectrum of Potassium excited during its Spontaneous Combination with Chlorine.

THE spectrum of ionised potassium has been studied by many scientists by exciting the vapour with the condensed spark, electrodeless ring discharge, and electronic impacts I have been recently studying the spectrum emitted by potassium burning in chlorine at normal pressure *spontaneously*, and have obtained the following interesting results

The photographs taken with the quartz spectrograph show a very strong emission band in the red extending from about 7200 to 6150, corresponding to the emission and absorption bands obtained by McLennan and Ainslie in the fluorescence and absorption spectra respectively of dense potassium vapour Besides this, many arc lines of moderate intensity and the following *enhanced lines* are seen

4466, 4388, 4307, 4220 and 4115

As the slit was kept fairly broad, some of the wavelengths given are the mean values for lines very close to each other

These results show that the *electron affinity* of the chlorine atom, together with the temperature attained by the potassium vapour as a result of the chemical reaction, must account for the excitation of the *enhanced lines* in the absence of any external electrical forces I am following up the work in connexion with the remaining alkali metals A

detailed account of the results obtained hitherto, along with an explanation of the processes involved in the emission of the enhanced spectrum, will be published shortly L. A. RAMDAS.

Heterogeneous Catalysis.

IN connexion with prevailing notions on heterogeneous catalysis, the following remarks of Graham, written in 1868 (Proc. Roy. Soc., 16, 422, 1868; "Chemical and Physical Researches," 1876, p. 286), would seem to be of interest. Referring to the adsorption of hydrogen by platinum, he says: "The hydrogen appears to be polarised, and to have its attraction for oxygen greatly heightened. I beg to offer the following representation of this phenomenon, with an apology for the purely speculative character of the explanation. The gaseous molecule of hydrogen being assumed to be an association of two atoms, a hydride of hydrogen, it would follow that it is the attraction of platinum for the negative or chlorylous atom of the hydrogen molecule which attaches the latter to the metal. The tendency, imperfectly satisfied, is to the formation of a hydride of platinum. The hydrogen molecule is accordingly polarised, *orienté*, with its positive or basylous side turned outwards, and having its affinity for oxygen greatly enlivened. It is true that the two atoms of a molecule of hydrogen are considered to be inseparable, but this may not be inconsistent with the replacement of such hydrogen atoms as are withdrawn, on combining with oxygen, by other hydrogen atoms from the adjoining molecules. It is only necessary to suppose that a pair of contiguous hydrogen molecules act together upon a single molecule of the external oxygen. They would form water, and still leave a pair of atoms, or a single molecule of hydrogen, attached to the platinum." (The formula of water is evidently considered to be HO.)

University of London

Influence of Radiation on Ionisation Equilibrium.

IN a recent letter (NATURE, March 14, p. 377) Saha and Swe develop the theory of the stationary state of a medium traversed by radiation of a temperature different from that belonging to the medium. Their argument seems to follow thermodynamic lines, supposing this to be the case, it may be of interest to point out how the same results may be obtained starting from Einstein's classical paper on Planck's radiation law (*Phys. Zeit.*, 18, p. 121, 1917) and from Milne's extension to the photo-electric effect (*Phil. Mag.*, 47, p. 209). The principle of this alternative method, already well known (Milne in this way recently has derived a formula equivalent to formula (3) of Saha and Swe, in his investigation of the equilibrium of a Ca^+ chromosphere, Mon. Not. R.A.S. 85, p. 119), consists in formulating the conditions required for a stationary state by means of probability laws governing the elementary processes involved. These probability laws themselves have been derived from the consideration that in thermodynamic equilibrium the number of elementary processes in one direction ought to balance the number occurring in the opposite direction.

For example, consider a gas traversed by radiation of a different temperature. Milne's results allow us to compute the ratio of the number of photo-electric ionisations to the number of electron-captures accompanied by emission of radiation, in terms of the relative concentration of neutral and ionised atoms. Requiring this ratio to be equal to unity furnishes a value for the degree of ionisation identical with formula (4) of Saha and Swe.

Observatory, Leyden,
March 23.

Bushmen Rock Figures.

THE comparisons made by Prof. Dart (NATURE, March 21, p. 425) between Bushman paintings and Asiatic figures will need much wider knowledge than we at present have on our side. The turn-over cap called "Phrygian" belonged to Phœnicians of Tyre and Sidon, and to men of Dabig between the Euphrates and Gulf of Alexandretta (see "Gates of Balawat"). It is seen about the Mediterranean now, and is much like the cap of the London draymen fifty years ago. The cap with the long tail is not only Babylonian, but is the typical head-dress of the Hittite and Syrian god Sutekh. Both of these forms may have a much wider spread, and the Bushman might have been figuring a liripipe hood of five centuries ago.

The Figure 13, quoted as Egyptian, is a man of Punt. The "figurino of an Egyptian courtier of the period of Thothmes III" I have handled. It is a well-known kind of moulded pottery figure, from Thebes, but more probably modern than ancient. There is, no doubt, a wide basis of African custom and culture below Egyptian civilisation, of which I have quoted dozens of examples, in *Ancient Egypt*, 1914, pp. 115, 159, and the indications are that these are due to a common basis, and not to importation from Egypt. General likenesses to Egyptian figures do not strike those who know them best, the women of Fig. 12 might be Somalis, but not Egyptians. Resemblances of names require an exhaustive inquiry as to possible meanings and origins among all the languages that may have intervened, before they can be accepted with caution. A name always means something, it is not a casual sound.

FLINDERS PETRIE.

Hampstead, N.W.3.

On the Resonance Radiation from Thallium Vapour.

RECENTLY we have shown that the absorption spectrum of non-luminous thallium vapour exhibits lines corresponding to the sharp and the diffuse series, and that $1\pi_2$ is the ground orbit of the valence electron in the atom of this element. A further confirmation of this view is given by our latest experiments on resonance radiation. In these experiments the radiation emitted from the vapour in a lateral direction was examined when the vapour was illuminated with light obtained by using different colour-screens. It has been found that the vapour, subjected to radiation $\lambda 5350$ ($1\pi_1 - 1\sigma$), does not emit any radiation, while when illuminated by radiation $\lambda 3775$ ($1\pi_2 - 1\sigma$) it acquires the ability of emitting radiations $\lambda\lambda 5350$ and 3775, the fluorescent track in this latter case being of a beautiful green colour. These experiments, together with the experiments on absorption, strikingly confirm that $1\pi_2$ is the normal state of the atom. Further experiments in this direction are in progress.

The Migrations of the Painted Lady Butterfly.

By C. B. WILLIAMS, Acting Chief Entomologist, Ministry of Agriculture, Egypt.

THE migrations of birds have been known for centuries, and have, particularly in recent years, been moderately well studied and understood. The migrations of fishes are also generally known, and within the last few years the remarkable journeys of the eel have been definitely determined. Most people know that locusts make huge migratory flights, invading countries in countless numbers and doing incalculable damage; but it is surprising how few are aware that such frail insects as butterflies make extended migratory flights, often in enormous numbers and over hundreds and even thousands of miles

Scattered throughout literature there are references to nearly two hundred species of butterflies which have been seen in migratory flights. In most of these there

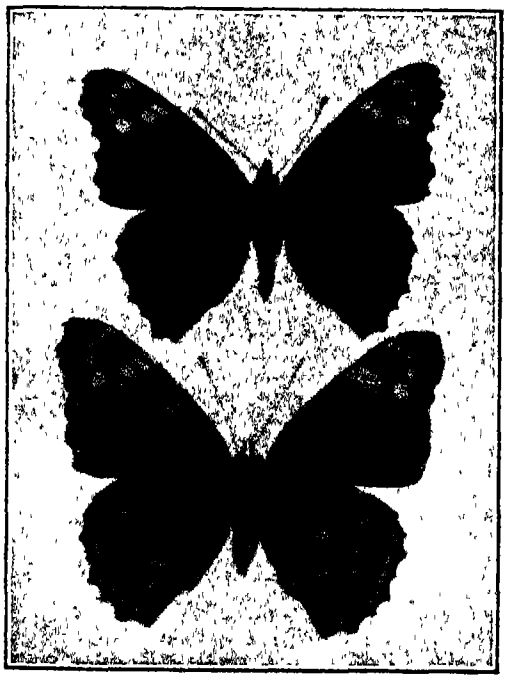

FIG. 1.—The Painted Lady or Thistle butterfly (*Pyrameis cardui*).

are unfortunately only one or two records for each species, and in only a very few cases do the records number more than a dozen. In two or three, however, we have sufficient evidence to get a general idea of the movement, and of these the most complete is that of the Painted Lady or Thistle butterfly, *Pyrameis cardui* (Fig. 1).

This butterfly, like many migrants, has a very wide range and is indeed known from every continent, and may be seen from the equatorial tropics to within a few degrees of the arctic circle. In Northern and Central Europe it is sometimes common, sometimes rare, and sometimes a summer will pass without a single specimen being seen. In England it is usually first seen at the end of May or beginning of June, and becomes again more common in August and September, but there is no evidence of an individual surviving the winter in any stage. The same seems to be true of all Europe north of a line through the middle of France and South Germany or Switzerland.

Observation has shown that north of this line the country is dependent for its Painted Lady butterflies entirely on migrations from the south. In the late spring, isolated individuals or huge swarms of this butterfly set their faces more or less to the north or north-west and, in Western Europe, cross France and England, and in some years may reach so far as Iceland. Farther east, similar migrating bands may fly from Italy or the Balkan peninsula, and cross Switzerland, Austria, Czecho-Slovakia, and Germany, and invade Scandinavia. Still farther east, in Russia, it is probable that the same movement occurs, but the records are few and far between.

Studying the movement in the south of Europe, we find that the majority of the migrating insects do not originate here, but cross the Mediterranean from North Africa, apparently finding but little difficulty in the long sea passage. Still more recently, evidence has been accumulating that even the north coast of Africa and Palestine do not represent the origin of the insect, and it appears that they reach the coastal regions of Africa from the south They have been recorded entering Algeria from the south; they have been seen crossing the Nile Valley near Cairo in thousands, coming from the south-eastern desert; they have been recorded as entering Palestine from the east in countless numbers for days on end, and finally comes a record of the same butterfly flying towards the west in Mesopotamia. They have been seen massed in great numbers, apparently resting during migration, in the Egyptian Desert near the Sudan border; but south of the desert belt, there is no record except a doubtful hint from Nigeria.

The present state of our knowledge of their movements in Europe, North Africa, and Asia Minor can therefore be summarised as follows (see also Fig. 2).

From somewhere in, or south of, or south-east of the long line of desert stretching across North Africa and Asia Minor, the butterflies begin their north and north-westerly movement in the early spring and arrive at the southern shores of the Mediterranean usually about April. From Palestine they appear to fly through Syria and Turkey to the Balkan States, and from Egypt, Tripoli, and Algeria they cross the Mediterranean, arriving in southern Europe usually early in May. They pass on, probably leaving behind stragglers all the time, and arrive on the level of the southern shores of England at the end of May or beginning of June, reach the northern part of Scotland about the middle of June, and have been recorded in Iceland in July.

The dates given are those of the first main drift, but the movement appears to continue for many weeks or even months at irregular intervals. Thus the butterflies have been seen crossing the Mediterranean north of Egypt so late as July, and in some years they appear to reach England from the Continent so late as September. These presumably are the progeny of later broods than the first movement. Apparently there is a general tendency for all butterflies over the whole

area to drift to the north-west during a large part of the year.

In other parts of the world there are also migrations, but the records are at present too few to be capable of discussion. They fly into California from the south in the spring at irregular intervals and have also been seen migrating in Florida. It is, however, only in Europe, North Africa, and Asia Minor that we can bind together the evidence into the semblance of a whole It is curious to note that in Ceylon, where migrations of many species of butterflies occur on a very large scale, one observer notes that *P. cardui*, although not uncommon, has not been noticed as entering into any of the flights.

As the migrations of birds are better understood than those of any other animal, it will be interesting to draw

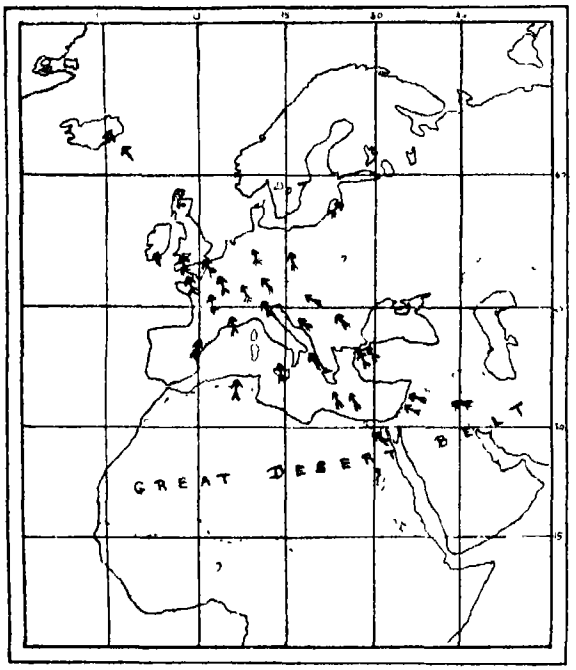

FIG. 2.—Sketch map indicating the known migrations of the Painted Lady butterfly

a comparison and see to what extent the migrations of the Painted Lady butterfly resemble them

In the first place, we have the remarkable fact that in the butterfly there is practically no evidence of any return from north to south in the autumn. So far as we can see, all those butterflies which fly to the north of the area in which they can breed throughout the year are lost completely to the species, as either they or their offspring perish during the winter The butterfly does not seem to have developed the ability to hibernate in any stage; unless it can breed continuously it cannot survive. The statement seems so remarkable that some investigators believe that there is a return flight, but that it is performed individually and not in mass, and so escapes notice. While this may be so, it is at present unsupported by any direct evidence and must be classed as an hypothesis, as opposed to the known facts of the northward movement in the spring. One cannot help referring here to the remarkable contrast which is found in the case of the Monarch butterfly (*Anosia plexippus*) in North America. Here the southward autumn flight is known from dozens of observations, while the direct evidence for the northward flight in the spring is extremely scanty, although from the complete absence of any record of hibernation in the Northern United States and Canada, we presume that such a return flight must occur.

The possibility must also not be overlooked that considerable flights may take place at night. This may seem to be a rather unexpected statement to be applied to butterflies, but it is actually supported by direct observation and capture of Painted Lady butterflies at night at light-ships and on boats at sea The same butterflies have also been seen flying to the north off the coast of Egypt between three and four in the afternoon, and to reach land in this direction they must fly all night or rest on the sea

In the case of the Painted Lady, it follows that even if there is a return flight, it is in a later generation. No individual butterfly ever performs the same journey twice, even in opposite directions, thus differing from most birds, which make the journey twice a year for several years This eliminates any possibility of memory being a factor in the determination of the route.

The next difference between the migration of the butterfly and most birds is that it is only a part of the butterfly population which migrates, while many stay behind to continue breeding in the countries where they hatched out If it is really true that there is no return flight, this of course would be absolutely necessary, as otherwise the species would gradually move northwards and become exterminated

Next we have the fact that while the migrants which reach England, for example, lay eggs and produce offspring there, those that have stayed behind in South Europe or North Africa are also breeding. In contrast to what is usually found in birds, breeding takes place throughout the whole range of the migration.

This raises the question as to whether it is the same individuals that perform the whole flight from Africa or Mesopotamia to Northern Europe, or whether the first migrants stop to lay eggs on the way and their offspring continue the flight later. The evidence at present indicates that the same individuals can, and in favourable years probably do, complete the whole flight, but that their progeny may also form a later migration, starting from where the eggs were laid by the original migrants, or may continue the migration alone if for any reason that of the previous generation has been brought to an end.

This in turn raises another question How is it that the butterflies have time to perform their long journeys, and, having hatched from a pupa in Africa, can wait to lay their eggs in England? The answer to this is still obscure, except that we know that *P. cardui* usually hatches out from the chrysalis with the generative organs completely undeveloped, but with a very large reserve fat-body. Apparently the migration generally takes place before the genital organs are functional (thus resembling the locusts); but this is not an absolute rule, as butterflies have been known to lay eggs while apparently on migration. When we know what determines the original development of the fat-body at the expense of the ovaries, and what later circumstances cause the ovaries to develop at the

expense of the fat-body, we shall be nearer the solution of one of the problems of migration.

Finally, as the life of the butterfly is not dependent on migration, we get another important difference from birds in the great irregularity of the occurrence and extent of the movement. Sometimes, as in 1879, Western Europe is invaded by countless millions, while in other years the migration is at a minimum and scarcely a single individual reaches the British shores. This irregularity of flight is probably an indication of varying conditions in the countries of origin of the swarms, but as we are not yet certain where these are or if they are always the same, it is idle to speculate as to what are the conditions that determine the start of the flight. Once the migration is in progress, what little evidence we have indicates that the direction is influenced, but not entirely determined, by the wind. The butterflies have a tendency to fly into the wind rather than with it, and there are one or two records, from localities with a daily change in wind direction due to land and sea breeze, of a corresponding daily change in the direction of the flight

This tendency to fly more or less into the wind would of itself partly account for the general trend of the migration to the north and north-west, as in the spring there are prevalent northerly winds over Southern Europe, the Mediterranean, and North Africa (see Fig. 3). However, one feels that this alone is not the explanation of the main trend of the flight, and further study and many more records are necessary before it will be possible even to guess at the real cause

We are similarly in ignorance as to what are the conditions which cause the insects to cease migrating—if it is fatigue, low temperature, food, or the development of the sex organs and sex instinct, and if the latter, the problem is only put one stage further back to what is the cause of this change.

The final question, which is with so many the first to be asked, is. Why do the insects migrate?

FIG. 3.—Prevailing winds in Europe and North Africa From Kendrew's "Climate of the Continents"

This is best perhaps at present left entirely alone. Whether, as some hold, a habit is explained when some advantage has been shown to accrue from it to the species, or whether, as I insist, there must be an immediate mechanistic cause for the migration of each individual, is a question the discussion of which would be out of place in the present article.

Further Evidence regarding the Correlation between Solar Activity and Atmospheric Electricity.[1]

By Dr. LOUIS A BAUER,
Department of Terrestrial Magnetism, Carnegie Institution of Washington, Washington, D C, U S A.

THE geophysical element which has thus far shown the most marked correlation between manifestations of solar activity, as, for example, sunspottedness and prominences, is some measure of activity of the earth's magnetism. The range of the magnetic diurnal variation, as shown by observations extending over nearly a century, is known to pass through a definite fluctuation to the extent of 50 per cent., or more, during a sunspot cycle. The synchronism between the solar curve and the magnetic curve is not exact, however, the times of maxima of the two curves differing not infrequently by one year or more. Thus, at the Kew Observatory the absolute daily range of the magnetic declination during the period 1858–1900, or approximately 4 sunspot cycles, passed through a maximum value, three times out of the four cases, one year *in advance* of the sunspot maximum. During the recent sunspot cycle (1913–1923) the maximum magnetic activity showed a lag of two years with reference to the solar curve. In 1893, when sunspottedness was a maximum, the earth's magnetic activity, after having been increasing for several years previous, was quite markedly lessened, and then rose to a maximum value in 1894

Attention may also be directed to the fact that no index of the sun's activity, as given thus far by solar observations, is apparently a complete measure of the radiations or emanations which are responsible for the magnetic phenomena just described. Nor do the solar measures in themselves, or for that matter the magnetic measures, give us a definite indication of the *sign* of the electrically charged particles which may be shot out by the sun during periods of intense activity.

The desirability is thus seen of finding some other geophysical element which may be affected in such a manner by solar changes as to supplement effectively the knowledge gained from magnetic effects and polar lights. That element may be atmospheric electricity; some results concerning the correlation of this element with solar activity were presented before these societies [2] a year ago. The present communication is based on atmospheric-electric data accumulated during the past 7 sunspot cycles. Manifestly, it will not be possible here to attempt more than a summary of the entire

[1] Presented before the joint meeting of the American Physical Society, the American Astronomical Society, and Sections B (Physics) and D (Astronomy) of the American Association for the Advancement of Science, Washington, D.C., December 30, 1924.

[2] See footnote 1.

investigation; those interested may be referred to the fuller publication.[3] Since atmospheric electricity is so continuously subject to much greater fluctuations of all kinds, natural and artificial, it will be appreciated that the tracing of a definite connexion with solar activity is much more difficult than in terrestrial magnetism, and, accordingly, an allowance must be made in the critical examination of the results. *So far as possible, only data derived from so-called electrically undisturbed days*, i.e. *days of no negative potential and no pronounced disturbances, have been utilised.*

ATMOSPHERIC POTENTIAL GRADIENT AND VARIATIONS.

In Table I., s represents the percentage change in the atmospheric element corresponding to a change of 1 in the Wolf-Wolfer observed sunspot numbers, and S_m the mean sunspottedness of a complete cycle beginning with the year of minimum.

Table I. summarises the average values of s, expressed in percentages of the respective electric quantity, for each of the 7 sunspot cycles beginning with 1843, derived from the observed values of the potential gradient, P, and some measure of its diurnal and annual variations.[4] The stations for which sufficiently long series are at present available for the various cycles are as follows: Brussels for Nos 1, 2, and 3; St. Louis, Missouri, for portions of Nos 2 and 3; Greenwich for No. 4; Perpignan, Lyons, Kew, and Greenwich for No. 5; Kew, Greenwich, Perpignan, and Kremsmünster for No. 6, and Ebro (Spain), Eskdalemuir, and Kew for No. 7. An attempt has been made in the last column to give some idea of the weight, w, to be attached to the tabulated s, according to the character of the available observations and number of stations utilised. Nos. 1 and 4 get the lowest weight (0·5), as they each depend on one station alone, no trustworthy observations at other stations for the corresponding period being at present available. No. 7, on the other hand, is given the largest weight (3), as it depends upon the most modern observations at three distant observatories; No. 6 ranks next in reliability. Though No. 5 depends on the data from several observatories, it is given a weight of but 1·5, as during the period covered the observations are all relative ones, the method of reduction to infinite plane not having as yet been introduced.

TABLE I.—VALUES OF SUNSPOT COEFFICIENT, s, FOR ATMOSPHERIC ELECTRICITY, 1843–1893

No.	Sunspot Cycle.	S_m	s (per Cent.)	w.
1	1843–1855	53·7	−0·70	0·5
2	1856–1866	49·6	+0·53	1·0
3	1867–1877	56·6	+0·22	1·0
4	1878–1888	34·6	+0·09	0·5
5	1889–1900	38·8	−0·24	1·5
6	1901–1912	31·1	+0·49	2·5
7	1913–1923	40·6	+0·24	3·0
Mean, Nos. 2, 3, 4, 6, 7			+0·34	8·0
Mean, Nos. 1 and 5			−0·35	2·0

It will be observed that for five of the seven cycles the sign of s is plus, which means that increasing potential gradient and diurnal and annual ranges corresponded with increasing sunspottedness, the average value of s being +0·34. For two of the seven cycles, namely, Nos. 1 and 5, the sign of s is negative, implying that increased potential gradient and ranges corresponded with decreasing sunspottedness, the average value of s being −0·35.

He who wishes to regard the two cases (Nos. 1 and 5) as contradictions of a definite correlation between atmospheric electricity and solar activity, may take the algebraic weighted mean of all values of s for the 7 cycles and obtain +0·20, which corresponds approximately to the value for the period (No. 7) of most trustworthy observations. However, I am inclined to advise leaving open the possibility of a reversed relationship, especially as the indications afforded by No. 5 are of a character not lightly to be dismissed. For example, the most striking part of the reversal occurred during the year 1893, when, as has already been remarked, there was also a notable depression in the earth's magnetic activity, in spite of its being the year of sunspot maximum,[5] this is the first definite correlation between disturbances in atmospheric electricity and terrestrial magnetism.

Comparing the values of s for the past two sunspot cycles, it will be observed from Table I. that, while they are both plus, the value for the cycle (No. 7) of more intense solar activity, as indicated by the mean sunspottedness, S_m, was only about one-half of that for the preceding cycle (No. 6). The same fact is found to apply to the values of s derived from two different measures of the earth's magnetic activity obtained independently by Dr. Bartels, of the Potsdam Observatory, and myself. The ratio of s (No. 6 : No. 7) is 2·0 for atmospheric electricity and 1·7 for terrestrial magnetism.[6] Even the variation during the year of s follows essentially the same law for both geophysical phenomena. Thus the ratio of s (October to March : April to September), for the period 1911–1921, was found to be 2·4 for atmospheric electricity and 1·7 for terrestrial magnetism. If a definite correlation is to be ascribed between solar activity and terrestrial magnetism, the facts just cited point to the conclusion that there is likewise a definite correlation between solar activity and atmospheric electricity.

Fig. 1 shows the high degree of correlation between solar activity and atmospheric potential gradient and its diurnal and annual ranges for the two sunspot cycles, 1901–1923, during which the atmospheric-electric data are of highest reliability. For the first cycle (1901–1912) we have available electric data at Kew, Greenwich, and Perpignan (France). For the second cycle (1913–1923) the data were obtained from the observatories at Kew, Eskdalemuir (Scotland), and Ebro (Spain). I desire here to acknowledge my indebtedness for latest data at these observatories to the very cordial co-operation in this research given by the respective directors.

While in the fuller publication the data from each observatory have been treated independently and

[3] *Terr. Mag. and Atmos. Elec.*, vol. 29 (1924), pp. 23-32 and 161-186.

[4] Table I. was derived from the values of s given *in extenso* in the author's Table 7, p. 171, *Terr. Mag.*, vol. 29, p. 171.

[5] See Fig. 2, *Terr. Mag.*, vol. 29, p. 31.

[6] While s for cycle No. 7 was only about one-half of that for No. 6, the total electrical output during each cycle may have been about the same. Thus if R is the range or difference in sunspot number between minimum and maximum, then we have for No. 7, $Rs = 102 \times 0{\cdot}24 = 24$, and for No. 6, $Rs = 61 \times 0{\cdot}49 = 30$.

without the use of any smoothing process, it was thought desirable in the graphs, Nos. 3, 4, and 5 of Fig. 1, to group them together as indicated and take smoothed means according to the well-known formula $(a+2b+c)/4$. With the aid of overlapping data for about two years, a preliminary attempt was made to refer the mean results for the two cycles to the same base line; a more accurate reduction will be possible later. Curve 5 is a combination of the results shown

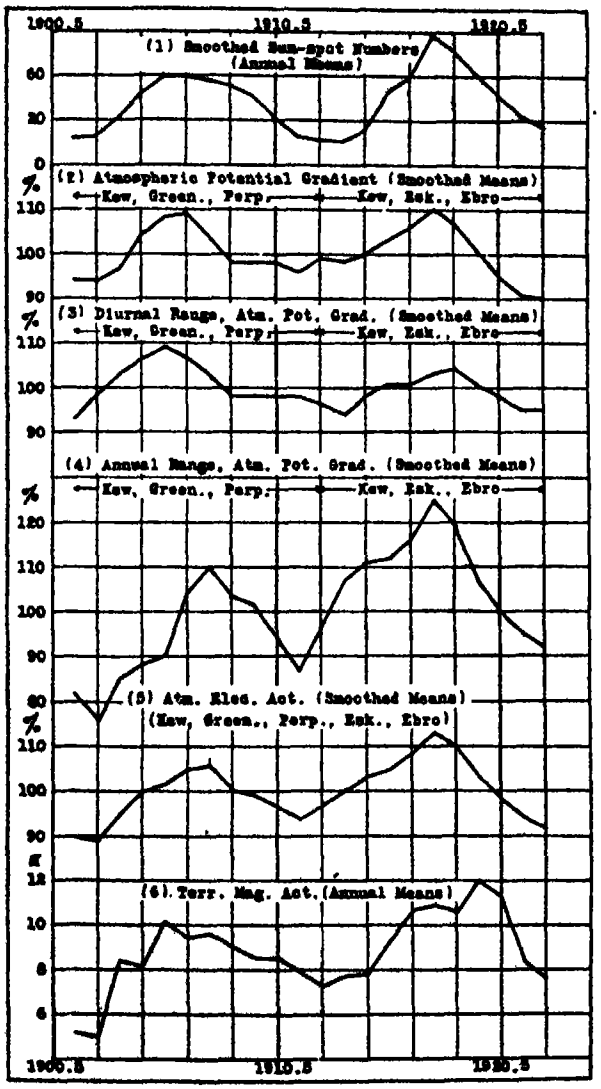

FIG. 1.—Showing degree of correlation between solar activity, atmospheric electricity, and terrestrial magnetism for the two sunspot cycles 1902–1923. (Dependent on atmospheric-electric data at Kew, Greenwich, Perpignan, Eskdalemuir, and Ebro, and on magnetic data at Potsdam, 1900–1905, and at Cheltenham, Maryland, 1905–1923.)

separately in Curves 2, 3, and 4. The smoothed sunspot numbers are those of Wolf and Wolfer with extensions according to latest data kindly supplied to me by Dr. Wolfer. Curve No. 6 of the measure of the earth's magnetic activity (ϵHR) has been derived by me with the aid of the absolute diurnal ranges (R) of the horizontal intensity (H) at the Potsdam Magnetic Observatory, 1900–1905, and at the Cheltenham Magnetic Observatory, Maryland, from 1905–1923; the data at the two observatories were reduced to the same basis and expressed in terms of the unit ϵ. For the most recent values of R at the Cheltenham Observatory, I am indebted to the Director of the United States Coast and Geodetic Survey. In the case of Curve No. 6 no smoothing was attempted, in order to obtain some idea how satisfactorily a measure of terrestrial magnetic activity might be obtained from one observatory alone, in view of the smaller effect of local disturbing influences in terrestrial magnetism than is the case for atmospheric electricity; however, since the atmospheric-electric data pertain to the electrically undisturbed days, only the magnetic ranges from the ten least disturbed days per month were used.

From Fig. 1 *the following conclusions may be drawn for the period 1901–1923*: (*a*) The atmospheric potential gradient and its diurnal and annual ranges show a high degree of correlation with the sunspot curve, increasing atmospheric-electric quantity in each case corresponding with increasing sunspottedness for both cycles; (*b*) the combined measure of activity as obtained from observations of the atmospheric potential gradient and its diurnal and annual variations at several stations may show as high a degree of correlation with sunspottedness as measures of terrestrial magnetic activity; (*c*) the annual means of the atmospheric potential gradient, of its diurnal range, and of its annual range follow closely parallel courses from year to year. (Conclusion (*c*) has been found to hold generally for the various cycles investigated.)

Table II will give some idea of the general agreement in the values of s, as derived separately from the observed values of the potential gradient, the diurnal variations, and annual variation at the three observatories. Eskdalemuir, Kew, and Ebro, for the region from Scotland to Spain and for the period of most trustworthy data, 1911–1921. The values of the correlation coefficient, r, are also given for each observatory; it will be seen that, for the potential gradient, r varies from 0·76 to 0·95, according to the location of the observatory, the mean value being 0·85. The mean value of r is lowest for the annual variation, as this quantity cannot be determined entirely satisfactorily from single years of observation. The mean value of s, it will be seen, is practically the same for each atmospheric-electric quantity.

TABLE II.—COMPARISON OF VALUES OF SUNSPOT COEFFICIENT, s, FOR VARIOUS STATIONS AND ATMOSPHERIC-ELECTRIC QUANTITIES, 1911–1921 (s is expressed in Percentages of Mean Values of Atmospheric-Electric Quantity.)

No.	Observatory.	Pot. Grad.		Diur. Var'n.		Ann. Var'n	
		s	r	s	r	s	r
1	Eskdalemuir .	+0·19	0·85	+0 20	0·53	+0 44	0·65
2	Kew. . .	+0 20	0 76	+0·17	0 58	+0·19	0·30
3	Ebro . .	+0 31	0·95	+0 33	0·78	+0·23	0 32
4	Means .	+0 23	0·85	+0 23	0 63	+0 29	0·42

VERTICAL CONDUCTION CURRENT AND ELECTRIC CONDUCTIVITY.

According to observations at Kew (1911–1921) and Ebro (1914–1923), the vertical conduction current of atmospheric electricity during the past sunspot cycle apparently increased with increasing sunspottedness,

at the average rate of 0·32 per cent. for a change of 1 in the sunspot number. As this is about the same average rate of change shown by the potential-gradient observations at the same two observatories, the present indications are that the average rate of change for several stations of the atmospheric-electric conductivity with sunspottedness, if not zero, is small. The continuous observations of negative electric conductivity at the Potsdam Observatory likewise indicate but little change with changing solar activity. (Since this paper was prepared it has been found, by a method[7] which minimises the effect of uncontrolled changes in the factor to reduce potential gradients to volts per metre over level ground, that the average value of s for the Potsdam observations from 1913–1923 was +0·27 per cent. of the mean value of the potential gradient, *i.e.* the potential gradient increased, on the average, with increasing sunspot activity Accordingly, the vertical conduction current at Potsdam also increased during 1913–1923 at the average rate of about 0 27 per cent for an increase of 1 in the sunspot number)

Atmospheric Electricity and Terrestrial Magnetism.

The foregoing results indicate a close correspondence between such changes in atmospheric electricity and terrestrial magnetism as may be dependent upon the state of the sun's activity from cycle to cycle However, the close correspondence between the two different geophysical phenomena also holds in other respects For example, the so-called "earth-effect" on sunspottedness during circumminimum years, the diurnal range of the atmospheric potential gradient, the diurnal range of the potential gradient of earth currents, the aurora borealis frequency for latitudes 51° to 58° north, and terrestrial magnetic activity all pass through a double periodicity during the year, the maxima and minima occur near the equinoctial and solstitial months respectively. Furthermore, the retardation of the second maximum from September to October is common to all phenomena For further explanation, reference must be made to the fuller publication.[8]

It would appear that terrestrial magnetism and fine weather atmospheric electricity are more closely associated than has heretofore been thought to be the case. Besides being subject to diurnal change, they both show similar fluctuations from year to year and from month to month. Whether atmospheric electricity, like terrestrial magnetism, is subject to a still longer cycle of changes than that of the sunspot cycle, seems not unlikely, and is the subject of further inquiry.

In a notable respect the changes of atmospheric electricity differ from those of terrestrial magnetism, namely, as regards relative magnitude. The periodic variations of the earth's magnetic elements are usually but fractions of 1 per cent. of the respective element, whereas in atmospheric electricity the diurnal and annual ranges, even for undisturbed conditions, may be of the same order of magnitude as the normal potential gradient itself. If such large percentage changes as 100, for example, are likely to occur in the potential gradient during the day and the year, it should not be surprising if there is, on the average, a 30 per cent. change between the years of minimum and maximum sunspottedness.

Is the Sunspot Influence Direct or Indirect?

While it may appear reasonable that atmospheric electricity does vary with solar activity, it is not possible to decide from *a priori* considerations whether the potential gradient ought to be high or low for maximum sunspottedness, as this depends on the *modus operandi* of the cause, the average sign of the electrically charged particles shot out from the sun, and whether the action is a direct or an indirect one. These are questions that must be reserved for future investigation So much interest has now been aroused in the subject that we may confidently look forward to a more careful control in future of atmospheric-electric measurements than has at times been the case, and to a wider distribution of first-class observing stations.

In conclusion, it will be of interest to refer to the fact that while the present investigation has had to be based almost entirely on the atmospheric-electric data at observatories in western Europe, the final values of the potential gradients observed aboard the *Carnegie*, in all oceans, show that the mean value of the potential gradient for 1917, the year of sunspot maximum, was about 20 per cent greater than the mean value in 1921, near the year, 1923, of sunspot minimum This result corresponds well with the average corresponding change at the western European observatories.

Obituary.

Prof. A. Dendy, F.R.S.

PROF. ARTHUR DENDY, whose death occurred on March 24, in King's College Hospital, at the age of sixty years, was educated at the Manchester Grammar School. On leaving school he proceeded to the Owens College, where he became one of a small band of distinguished zoologists trained by the late Prof. A. Milnes Marshall. He was the first of the students of the old Victoria University to gain a place in the honours school of zoology. Soon after he took his degree in 1885, he went to the Biological Station at Millport, and as a result of the work he did there he published his first two papers, one on a twelve-armed specimen of Antedon and the other on the regeneration of the visceral mass of the same crinoid.

Although Dendy never lost his interest in the group of Echinodermata, it was for his wide knowledge and brilliant researches on sponges that he was destined to become a world-wide authority. He was called to London as an assistant in the British Museum (Natural History), and undertook to complete for publication the memoir on the monaxonid sponges of the *Challenger* expedition, which had been left unfinished owing to the serious illness of Mr. Stuart Ridley. He set to work with his characteristic energy and skill, and this "highly satisfactory" memoir was published in 1887.

In the following year Dendy was appointed lecturer in zoology in the University of Melbourne, a post he held until 1894, when he was promoted to the professorship in the same subject in the Canterbury College of New Zealand.

In the rich and extremely interesting fauna of Australasia, Dendy found full scope for his brilliant abilities in zoological research, and he published in rapid succession a long series of papers on the anatomy and development of some of the most interesting animals of that region. Apart from some excellent papers on sponges, he wrote on land planarians, on the land nemertine (Geonemertes), on the remarkable polyzoan Cryptozoon, on Holothurians, and on the Collembola. His valuable papers on the oviparous species of Peripatus greatly enriched our knowledge of this extremely interesting and archaic arthropod, and his study of the pineal eyes of the New Zealand lamprey Geotria threw important light on the history of these remarkable vestigial structures previously discovered in Sphenodon by his friend—also an old Owensian—Sir Walter Baldwin Spencer. On reaching New Zealand he lost no time in going in search of Sphenodon itself, and, on finding that there was serious danger that the enterprise of collectors would lead to its early extinction, he made urgent and successful appeals to the Government to pass measures for its protection He was the first to write an account of the development of this reptile, and to record many important features of its anatomy and natural history.

In 1902 Dendy came back to England on a visit, and was given the hospitality of the Zoological Department of his old University in Manchester to enable him to pursue some investigations on which he was engaged Here he completed his description of the aberrant floating hydroid Pelagohydra and examined sections through the brain of the Ammocoetes larva In studying the anatomy of the Geotria in New Zealand, he had discovered a pair of ciliated grooves lying beneath the posterior commissure of the brain, and he found these grooves to be even better developed in the brain of the young Petromyzon. On these researches he published an interesting paper, which appeared in the Proceedings of the Royal Society in 1902. His studies on these brains led him to the investigation of another structure in the nervous system of vertebrates, namely, Reissner's fibre. On this subject, also, he made a very important communication to the Royal Society in 1910.

While he was in England on this visit, Dendy heard of the vacancy in the chair of zoology at Cape Town. He applied for the post and was appointed. But he remained in South Africa only two years, as he received the appointment to the professorship in King's College, London, in 1905, vacated by the retirement of the late Prof. F. J. Bell. He held this chair until his death. He was elected a fellow of the Royal Society in 1908.

In London Dendy carried on his teaching and researches with increasing energy and success, and under his guidance King's College soon became recognised as an active centre of research in his subject. He put together some of his teaching notes in the form of a book entitled "Outlines of Evolutionary Biology," which was published in 1912 and has already reached a third edition, and he also wrote an interesting little book entitled "The Biological Foundations of Society," which was published in 1924.

The last important work he wrote was the memoir on the Antarctic sponges reviewed in NATURE of March 7, p 330, but a preliminary note published in these columns on February 7 showed that he had in hand a paper in which he was prepared to maintain the rather startling proposition that the spicules of siliceous sponges are formed by the skeleton-forming cells enveloping migratory symbiotic organisms resembling micrococci. Many of his friends looked forward with much interest to the fulfilment of his promise made last December to maintain this thesis at the next meeting of the British Association.

Dendy was a man with a very striking and impressive personality, a fine speaker, and a clear and sympathetic teacher. His father was a well-known Unitarian minister. One of his sisters, Miss Mary Dendy, is widely known for her philanthropic work, particularly in connexion with the care and education of feeble-minded children. Another sister married Dr. Bernard Bosanquet, and is herself a well-known writer.

S. J. H.

WITH the sudden and untimely death of Prof Dendy, we have lost the only man in England with a catholic knowledge of sponges, and probably the leading authority of the two or three in the world who could be classed with him He was a biologist with wide scope of learning and research as well as a spongologist, but it is of his work on sponges only that I am competent to write

A catalogue of Dendy's papers on sponges would be long. They begin in 1886, when he was twenty-two, with Ridley and Dendy's "Preliminary Report on the Monaxonida . . . *Challenger*"; they end with a letter, unseen by me as I write this (March 26), which appears in NATURE for March 28, and shall remain in these columns unanswered. Ridley and Dendy's classic *Challenger* monograph (1887) was written as to some five-sixths by Dendy, a wonderful piece of work for so young a man Then came careful anatomical and histological studies of single species (*Q.J.M.S.*, 1888 *et seqq.*). Beside them the "Monograph of the Victorian Sponges . . . Homocœla" (1891) described several important new forms, of some of which we have little added information—one is now recognised as of generic rank by the name Dendya, not conferred by its discoverer. But the contemporary importance of the "Monograph" was that it carried on Poléjaeff's revolt (*Challenger* "Calcarea," 1883), and struck loose from Haeckel's "Kalkschwamme," and in this it was followed by "Observations . . . and Classification of the Calcarea Heterocœla" (1893, *Q.J.M.S.*), which made a serious and valuable attempt at classification *de novo*.

It would be a long article which should follow Dendy from youth to maturity and from maturity to the admirable work of his last years; we may say briefly that Vosmaer's "Bibliography" to 1913 (in press) gives him thirty-five publications, mainly before 1898, and that his masterly "Reports" since 1913 on collections of sponges add up to 460 quarto pages of print. They are all good As in other descriptive monographs, there is much which is only readable to the colleague whose interest has been aroused in the

organism described. But there is no slovenly work, and nothing written without purpose, responsibility, and accuracy.

Dendy was above all truthful in record. I have followed much of his work very closely in calcareous sponges, and I have never found the sign of anything described which I had reason to doubt had been seen. He was a beautiful draughtsman, and I have always considered that I could trust one of his drawings as if I had seen the specimen Four or five years ago I questioned him as to certain details in his early illustrations (*a*) of the collar-cells of Halichondria, (*b*) of the pore-canals of *Leucosolenia stolonifer*. He showed me under the microscope the actual sections from which the drawings had been made, a third of a century earlier, and the fidelity was perfect

Dendy's life's work as regards sponges was to accomplish a revised classification of the whole group and of their spicules. He was an evolutionist to the core, and believed in the evolutionary chain not only for all forms of sponges but also for all their spicules. His work, however, led him to the conclusion that it is impossible to consider the detailed form of spicules to be evolved for functional advantage to the sponge, and in the case of the two-disced spicule of Latrunculia he, in conjunction with Prof. J. W. Nicholson, gave a most important physical theory of the nodal position of the discs.

I have elsewhere expressed disagreement with his classification. But Dendy had investigated probably more forms of sponges than any one else has ever done, unless possibly Topsent, Hentschel, or Vosmaer. His works constitute a logical catalogue of their forms and of their spicules, illustrated almost entirely by himself with innumerable accurate drawings and accompanied by clear and careful description. He has made research on sponges easier for all who come after him; he has left order where there was much chaos

Dendy enjoyed public discussion and hard hitting, given and received without disturbing private friendship Veracity in record, swift work, accurate observation, clear description, untiring industry and enthusiasm for biological knowledge—these were his characters.

In ten years have died Minchin, Maas, Vosmaer, Dendy The evening grows chilly.

GEO. P. BIDDER

MR. THOMAS HUGH POWELL, who died in London on February 19, was a remarkable personality in the microscopical and photographic world He devoted practically the whole of his life to the development and improvement of appliances in connexion with microscopes and photography, and, following in the footsteps of his father, Mr. Hugh Powell, was responsible for many progressive inventions. When Mr. Powell's father died in 1883, it was said of him in an obituary notice in the *Times* that he was the first optician in England to construct object glasses on Amici's "immersion" system. After making a considerable number of one-eighths, one-sixteenths, one-twenty-fifths, and one-fiftieths, he completed, with the assistance of his eldest son, who has just died, an object glass of this kind having a focal length of one-eightieth of an inch. The formula of the "homogeneous immersion" system was the subject of special attention on the part of Mr. Powell, sen., but failing health compelled him to rely on the efforts of his son, by whom object-glasses on this formula, having the highest apertures on record, were constructed. Mr. Powell was within a month of his ninety-third birthday at his death, having been born in March 1832. He was believed to be the oldest member, both in age and in length of membership, of the Royal Microscopical Society and the Quekett Microscopical Club, and displayed an active interest in his life-work to within a short time of his death.

WE much regret to record the death of Mr. Robert Standen, Senior Assistant-keeper in the Manchester Museum, who died on March 15, aged seventy-one years. He was born at Goosnargh, near Preston, and spent his whole life in Lancashire, forming one of the band of first-rate field naturalists who have done so much work on the fauna and flora of the north-west of England. He had wide knowledge and experience, and would have something of interest to say about most of the live things met with on a country walk, and to this he added a skilful museum technique and a scholar's knowledge of his special group—mollusca—on which he wrote many papers both on the British and, in conjunction with Dr. Cosmo Melvill, on foreign forms. In recent years he was active in promoting interest in neglected groups and quickly made himself an authority on wood-lice: here and everywhere he never grudged time and trouble spent on helping any one who asked for assistance. His services to natural knowledge were recognised by the M.Sc. degree which was conferred upon him by the University of Manchester in 1924.

THE issue of the *Physikalische Zeitschrift* for February 15 contains an obituary notice of Gustave Jaumann, professor of physics in the Technical School of Brünn, from the pen of his colleague Dr E. Lohr. Jaumann was born at Karansebes in South Hungary on April 18, 1863, and was educated in Prague and Vienna. In 1885 he became assistant to Mach at the University of Prague, in 1893 professor of physics there, and in 1901 at Brünn, where he died suddenly on July 21, 1924. He published a number of experimental investigations on electric discharges and cathode rays, but is probably best known by his theoretical work, which is in great measure co-ordinated in his 1918 paper on the physics of continuous media.

THE editors of the *Journal of Genetics* inform us that they have received, with great regret, news that Mr. V. Issayev, of the University of Leningrad, has been killed in the Caucasus. The last number of that Journal contained a remarkable memoir by Mr. Issayev, giving the results of novel and curious experiments on grafting different species of Hydra together (noticed in NATURE, March 21, p. 438).

WE regret to announce the following deaths:

Mr W. W. Rouse Ball, fellow and formerly tutor of Trinity College, Cambridge, on April 4, aged seventy-four.

Prof. Burt G. Wilder, professor of neurology and vertebrate zoology in Cornell University from 1867 until 1910 and afterwards emeritus professor, and president in 1885 of the American Neurological Association and in 1898 of the American Association of Anatomists, on January 21, aged eighty-three.

Current Topics and Events.

A LETTER sent to us addressed from the Nanking Branch of the Science Society of China is of particular interest now that the China Indemnity (Application) Bill, having passed the Committee stage, is down for third reading in the House of Commons It is satisfactory to learn from the writer, Mr. Co-Ching Chu, that this important Society is in full agreement with our editorials of August 30 and November 29 last, not only on the principles and the chief details of expenditure there enunciated, but also on the object underlying our proposals, namely, the promotion of mutual understanding and goodwill between England and China At the same time our correspondent utters a word of warning to our legislators Expenditure on purposes other than educational and cultural may, he says, help to prolong the political turmoil in China, and to increase the antagonism towards foreigners Coming from a responsible Chinese, these are arresting words. It is, however, unfortunate that he credits the unfounded rumour that the change of personnel on the Advisory Committee indicates a reversal of policy, by turning from education to railways, and in particular to a line along the Yangtze Valley

ALTHOUGH railway construction is not ruled out by the vague wording "educational or other" purposes which Mr M'Neill has persistently retained in the China Indemnity (Application) Bill, such usage has been expressly disclaimed by him in recent debates He specifically declared to the Standing Committee that, while the main object of this Government, as of the last, is educational, the Government refuses to pledge itself even to education, if some other ameliorative object urgently presents itself While such an attitude is understandable in normal circumstances, it is not merely unstatesmanlike but futile now when an anti-foreign feeling is gathering head in China, and the Chinese are accepting the views pressed by nationalistic agitators that the remitted moneys are all of the nature of returned loot In any event, the sums remitted are so small when the size and the needs of China are considered that if distributed in driblets, as seems contemplated, no appreciable result will ensue Certain institutions will, of course, benefit, but so far as the goodwill behind our gift is masked by vagueness, our allocations, however carefully considered, will make no call on the goodwill of a responsive people, while the timid handling of co-operation, contrasting unfavourably with that of other remitting Powers, will do nothing to stem the tide that day by day runs more strongly against the foreigner and all his works.

A SMALL volume by Dr. Marie Stopes, entitled "The First Five Thousand," being the first report of the results achieved by the Birth Control Clinic established by Dr. Stopes and her husband at Marlborough Road, Holloway, has been published by Messrs. John Bale, Sons, and Danielsson, Ltd. That some form of birth-control is the only means of regulating the tendency of the population of Great Britain to increase beyond the limits of our food supply is a conclusion which has forced itself on more and more thinkers, both in the biological and economic spheres But birth-control is a subject against which more emotional prejudice can be aroused, than against almost any other subject of discussion In the volume before us Dr. Stopes gives a full, clear account of the foundation and organisation of the clinic, and of the care that is taken to prevent the knowledge imparted from being used for purely immoral purposes The sound rule is adopted that full advice is given only to women who have already borne one child Dr. Stopes is fully convinced (perhaps some of her critics think too fully convinced) that the method which she adopts is the only safe and innocuous one, but she certainly brings forward strong evidence in support of her contention, for out of 5000 cases she can only find evidence of 42 failures, whereas to judge from the figures which she gives, the percentages of *successes* when other methods have been employed has never risen above 25 per cent. Dr Stopes would perhaps admit that the storm of criticism, of which she has been the target, has led her to perfect the means employed, so that these criticisms shall be deprived of their ground After all, there is no getting away from the fact that the practice of birth-control is widely spread among the middle classes, and to deny the knowledge of the means to the poor, who need it far more than the middle-classes do, is a proceeding which no parliamentary language is strong enough adequately to criticise

THE Chemistry Section at the British Empire Exhibition this year is again being organised by the Association of British Chemical Manufacturers. In a purely business exhibition, designed to bring buyers and sellers together, a chemical display necessarily consists of samples of products This year's exhibit, however, will be designed mainly to interest the public and give the visitor some idea of the extraordinary part which chemistry plays in the national life. For example, instead of the individual dyestuff makers each having their own display, there will be a large combined exhibit which will show, not only the immense variety of articles into which colour enters, but also what beautiful effects can be obtained by the use of dyestuffs made in Great Britain. The Scientific Section, which created so much interest last year, will also be remodelled The public has now some idea of the position of Great Britain as a leader in scientific research It is proposed, therefore, to show how strikingly connected are the various stages in manufacturing processes, from basic materials to the finished product This subject will be treated by taking as a basis coal, salt, and food From the consideration of, for example, the raw coal, the visitor will be taken through the various stages of distillation of coal, the products of such distillation, such as tar and ammonia, the treatment of tar, and the resulting intermediate products which lead up to the manufacture of dyestuffs The production of benzol, of disinfectants, of fine chemicals, of medical products,

and the numerous other chemicals obtained from coal will also be illustrated. In this way it is hoped to demonstrate the importance of chemistry and chemical research in our daily life

"CHEMISTRY IN THE SERVICE OF THE STATE" is the title of a brochure, published by the Department of Chemistry of the University of Wisconsin, which sets out clearly and concisely the importance of chemistry in industry and in private life. Unlike some recent propaganda, this publication is practically free from overstatements, and within its limits it may be said to constitute an exceedingly able presentation of the case, it indicates in plain language the relations of chemistry to agriculture, to medicine, and to some important industries, and outlines briefly a few of the urgent problems that await solution The value of chemistry as a handmaid to other sciences appears to be well appreciated in Wisconsin, for we read that 89 per cent of the 1380 university students who took chemistry in 1923 were specialising in other subjects Perhaps the weakest section of the pamphlet is that concerning the cultural value of chemistry, but the weakness resides largely in the subject itself, for chemistry is essentially a material science, and culture connotes much more than a knowledge of the transformations of matter The authors therefore do well to emphasise the value of chemistry as a field for the exercise of the scientific method, but the implication that ability acquired in this sphere is transferable to everyday life would be strenuously resisted by many modern psychologists Further, the artist and the moralist would demur to the statement that the main business of life is to adapt ourselves to our environment. Does not the chemist himself seek to make his environment subservient to his own ends?

THE Ministry of Agriculture has recently issued a brochure of eight pages entitled "Wasps" Information is sought by numerous inquirers every season as to the species of wasp that happens to have attracted notice, while queen wasps are frequently mistaken by the uninitiated for the larger species or hornet These difficulties should be got over by the present publication, since all the seven species of British social wasps are clearly described in non-technical language, while identification is further aided by the remarkably well-executed coloured figures of all the species The letterpress includes a short account of the habits, nest-building, methods of destroying nests, etc., together with some cautiously worded observations on the food of wasps. The reader will gather from the facts brought forward that, although wasps may prey upon a certain number of noxious insects they are, on the whole, not to be regarded as beneficial The recent innovation of issuing pamphlets of a fuller nature than the usual leaflets of the Ministry, and illustrated by coloured plates, is to be commended. Various insects of economic significance require this fuller method of treatment, and it is to be hoped that the practice will be extended Brochures of a similar character on the frit fly, wireworm, certain fruit pests and other subjects would probably meet with a wide demand. Characteristic damage to plants by pests is often made far more easily recognisable to the agriculturist and fruit-grower through the medium of accurate coloured illustrations than by detailed descriptions and black-and-white figures The wasp pamphlet is priced at the low figure of 4*d*, post free, and can be obtained from the Ministry's Offices at 10 Whitehall Place, London, S W 1

THE output of mathematical research from the Masaryk University, founded in Brno in 1919, is already such as to show that an active school of post-graduate mathematics has been instituted there. A parcel of 46 recent memoirs, edited by M. Hostinský, and issued separately in Brno as "Publications de la Faculté des Sciences de l'Université Masaryk," contains research work, mainly on pure mathematics, carried out recently by some twenty authors in Czechoslovakia Typical examples are Hostinsky's "Notes sur l'équation de Fredholm," "Kolaček's "Les tremblements de terre Carpathiques sur le territoire de la République Tchécoslovaque," Kaucky's "Sur une équation singulière de Volterra de première espèce," Seifert's "Remarques sur une surface cubique à point uniplanaire," Boruvka's "Sur les racines imaginaires de l'équation $\Gamma(z)=a$," and Lerch's "Études sur la théorie des résidus quadratiques suivant un module premier" Most of the memoirs are printed in Chech, and followed by a French translation or abstract Nearly all of them show that the authors are familiar with the literature of their subjects As a whole they prove how seriously scientific research is being pursued in a new university, despite the economic conditions of eastern Europe If this rate of progress is maintained we foresee that the world of science will soon reckon the Masaryk University to be on a par with universities supported by greater wealth and with more age and tradition behind them.

THE question of the seat of the mechanism of aural analysis was brought strongly into notice some years ago by the publication of Sir Thomas Wrightson's "Analytical Mechanism of the Internal Ear." In that book, Wrightson, supported by Sir Arthur Keith, gave reasons for the view that the internal ear does not contain any analysing mechanism, that the individual nerve fibres have no characteristic individual function and act only in mutual support as transmitters of influence to a cerebral centre of analysis On that view the ear misses the opportunity of analysis which Helmholtz regarded the basilar membrane as furnishing Holders of it scarcely give sufficient weight to the knowledge and scientific judgment of Helmholtz when they conclude that the membrane cannot act as he considered it to do. A recent publication, "The Mechanism of the Cochlea," by Drs. Wilkinson and Gray, gives strong support to Helmholtz's view by means of scaled models. In "Some Questions of Phonetic Theory," chap. vi. (separately published), Dr. W. Perrett criticises adversely Wilkinson's and Gray's discussion. Unfortunately, the sarcastic style in which a large part is written is scarcely appropriate in a scientific discussion.

IN the annual address to the Asiatic Society of Bengal, delivered on February 4, the president, Sir Rabindra Nath Mookerjee, exhorts the members of the Society to renewed activity and appeals for the support of Princes and Zamindars as well as commercial magnates to enable the Society to continue and extend its work. The present position of the Society is one of considerable moment to those in Great Britain who are interested in those researches in India with which the Society concerns itself, and it may be hoped that the exhortations of the president will bear fruit. The address, which is a summary of the history and achievement of the Society since its inception in 1784, provides much material for reflection on the social and political changes which have taken place in that period in their relation to Indian studies. It is noted that whereas at one time research was largely, indeed almost entirely, in the hands of Indian Civil Servants, officials have now almost ceased to take any part in the Society's work, and there has been a great falling off in the interest shown by Europeans generally. The Society has great traditions, and European students now look to the natives of India to carry on these traditions worthily.

IN the issue of *Science* for February 20, Prof. Richard Hamer, of the University of Pittsburgh, Pa., enters a plea for naming the missing element of atomic number 43 before it is discovered; in view of the work of Bosanquet and Keeley (*Phil. Mag.*, 1924 (6), 145-147) and of others, he thinks that the discovery cannot be long delayed, and also that by taking time by the forelock in this manner, subsequent controversy, like that which followed the discovery of hafnium, will not arise. Prof. Hamer appeals to the scientific world to name the element "Moseleyum," in honour of the young British physicist who fell in Gallipoli, and to give it the symbol "Ms." In our view it would be a fitting tribute to the brilliant work of Moseley to perpetuate his name in some such way. Hitherto, no chemical element has been named after an individual (we exclude mercury, tantalum, thorium, and titanium for an obvious reason), and opinion may be divided on the advisability of making the innovation. It is, however, a mistake to be bound by precedent in such a matter, and the only objection we can foresee to the adoption of Prof. Hamer's suggestion is that the word is not particularly euphonious, and is rather suggestive of certain sepulchral monuments; but it might be argued that even this suggestiveness is not inappropriate, inasmuch as mausoleums are erected, as a rule, to the memory of the illustrious dead.

PROF. F. SODDY, professor of chemistry in the University of Oxford, has been elected a corresponding member of the Russian Academy of Sciences.

THE period of Summer Time in Great Britain will begin this year at 2 o'clock Greenwich mean time on the morning of Sunday, April 19. Summer Time in France and Belgium began on the night of Saturday-Sunday, April 4-5.

PROF. W. WIEN, professor of experimental physics in the University of Munich, will deliver the tenth Guthrie Lecture of the Physical Society of London on Friday, April 24, at the Imperial College of Science, South Kensington. The subject of the lecture will be "Recent Researches on Positive Rays."

AT the meeting of the Royal Geographical Society on Monday, April 6, the president announced that His Majesty the King has been pleased to approve the award of the Royal Medals of the Society as follows:—the Founder's Medal to Brig.-Gen. the Hon. C. G. Bruce for his life-long geographical work in the exploration of the Himalaya culminating in his leadership of the Mount Everest Expeditions of 1922 and 1924; the Patron's Medal to Mr. A. F. R. Wollaston for his explorations and journeys in Dutch New Guinea, Central Africa, and many other parts of the world. The Council has made the following awards:—the Murchison Grant to Mr. Eric Teichman for his travels in China and Tibet, the Back Grant to Capt. Bernier for his work in the Canadian Arctic, the Cuthbert Peek Grant to Mr. Michael Terry in support of his proposed journey across Northern Australia; and the Gill Memorial to Major R. E. Cheesman for his journey to the deserts of Jafura and Jabrin.

IN order to preserve the fauna of the Southern Ocean the Government of France has issued a decree constituting a national Antarctic reserve in certain territories belonging to France. According to *La Geographie* for January, the reserve includes all the Crozet Islands, St. Paul and Amsterdam Islands, and on Kerguelen certain islets on the north coast and parts of the south coast to a depth of 1000 metres from the land. Within these areas it is forbidden to hunt whales, seals, or sea-birds. No special means are proposed for enforcing these prohibitions, which must naturally depend on the good faith of the hunters who frequent these seas.

DURING two months following the Japanese earthquake of 1923, Mr. H. M. Hadley examined several hundred buildings in Tokyo and Yokohama that were damaged by the earthquake as well as several hundred others that escaped injury (Bull. Seis. Soc. of America, vol. 14, 1924, pp. 6-8). His general conclusion is that, whatever the material used—whether the buildings were steel-framed, of reinforced concrete, of brick or of wood—those that escaped were so framed and braced that they moved as a whole when their foundations were shaken. Of the large steel-framed buildings in Tokyo, those undamaged owed their immunity to the extensive use of reinforced concrete wall construction. A small amount of properly distributed wall construction at the corners and elsewhere was sufficient to protect buildings from the slightest damage. But, though earthquake-proof construction can be secured with any material, the safest and most economical results can be obtained "with structural steel or reinforced concrete, both embodying an adequate amount of reinforced concrete wall construction."

A REPORT on the meteorological service of Australia for the year 1922–1923 has been submitted to the Parliament of the Commonwealth by Mr. H. A. Hunt, the Commonwealth Meteorologist. The report deals with the Central Weather Bureau at Melbourne and with the Weather Bureaux at Sydney, Brisbane, Adelaide, Perth, and Hobart. At the Central Weather Bureau at Melbourne, reports are received daily from a large number of stations, embracing the adjacent islands, and from stations in New Zealand. By the aid of these reports, the South Pacific Islands are warned when cyclonic conditions are developing. The data are also used for the ordinary storm-warning service for the protection of the Queensland and New South Wales coasts and of shipping traversing the waters eastwards from Australia Rainfall maps showing the total rainfall for each month for several stations are published on the first day of the following month. Aviation forecasts are regularly issued, and the Aviation School at Point Cook is informed whenever easterly gales are expected; the latter seems an admirable precaution Ocean forecasts and storm-warnings, in addition to being distributed to coast stations, are broadcasted to ships at sea. The prevailing conditions of the weather round the coast are also supplied to radio stations. A careful analysis is made of the forecasts, on the average of fourteen years, the official forecasts verified for the States and for the Commonwealth as a whole reaches 87 per cent. There are 484 climatological and 5912 rainfall stations distributed throughout the Commonwealth and the adjacent territories.

Our Astronomical Column.

NEW COMETS —Still another comet, 1925 *c*, has to be added to the list of discoveries It was discovered by Mr. Orkisz in Russia on April 4, and was observed by Mr. Moller, at Copenhagen, on April $5^d\ 2^h\ 52{\cdot}7^m$ G.M.T. in R.A. $22^h\ 26^m\ 45\ 13^s$, N. Decl. 16° 37′ 19″. The motion in R.A. is small, that in declination is about 1° daily northward. The magnitude is 8. The comet is in Pegasus, and must be looked for in the east just before dawn

Both Schain's and Reid's Comets were observed by Dr Steavenson as follows.

Comet	G.M.T.	R.A. 1925.0	Decl. 1925.0
Schain	Apr. $2^d\ 1^h\ 55\ 6^m$	$11^h\ 31^m\ 26{\cdot}1^s$	+ 2° 27′ 37″
,,	,, 3 22 42·8	11 28 11·0	+ 2 35 49
Reid	,, 2 1 6·4	13 21 47·7	− 22 22 49
,,	,, 4 0 40·9	13 19 32·7	− 22 53 54

The following orbit of Schain's Comet is by Dr. A. C. D. Crommelin It is still subject to appreciable correction, but is much nearer the truth than Kobold's orbit, which made perihelion occur in November 1924.

T	1925 Nov. 2·58 G.M.T.	
ω	216° 35 5′	1925·0
Ω	357 30 6	
i	146 6 9	
log q	0·59512	

The perihelion distance is the second greatest on record, being exceeded by that of the comet of 1729 alone

EPHEMERIS FOR 0h GREENWICH

	R.A.	N. Decl.	log r	log Δ
April 11	$11^h\ 16^m\ 4^s$	3° 6′	0·6351	0·5355
,, 19	11 3 24	3 36	0·6323	0·5438
,, 27	10 51 56	3 59	0·6296	0·5546

The comet should be in sight for two years or more. It is at present not far from the orbit of Jupiter.

The following orbit of Reid's Comet is by Mr Moller and Miss Vinter-Hansen, of Copenhagen Observatory Almost identical elements were found by Mr. G. Merton

T	= 1925 July 22·951 G.M.T.	
ω	= 244° 19 8′	1925·0
Ω	= 7 41 6	
i	= 30 14·8	
log q	= 0·29608	

EPHEMERIS FOR 0h GREENWICH.

	R.A.	S. Decl.	log r	log Δ
April 10	$13^h\ 12^m\ 35^s$	24° 25′	0·3693	0·1345
,, 14	13 7 26	25 25		
,, 18	13 2 6	26 23	0·3601	0·1194
,, 22	12 56 39	27 19		
,, 26	12 51 12	28 12	0·3513	0·1099

The comet is fairly bright, with a distinct nucleus, but is too low down for convenient observation in England

SPECTROSCOPIC PARALLAXES OF 520 STARS OF TYPES F TO M.—Mr. W. B. Rimmer in vol. 64 of the R.A.S. Memoirs gives a full discussion of the absolute magnitudes and parallaxes of 520 stars from observations at the Norman Lockyer Observatory, Sidmouth. The curves connecting strength of lines with absolute magnitude were deduced from (1) moving-cluster parallaxes, (2) parallactic motion, (3) trigonometrical data; the last fails for the distant stars of high luminosity.

Special attention was given to the exact spectral type of the stars, published results being revised in several cases. Comparison of results is made with those of the Dominion Observatory, Victoria, B.C., the agreement being satisfactory.

On the whole the new parallaxes slightly exceed the trigonometrical ones, but the mean difference is only about 0·002″. The parallax of Polaris is given as 0·014″, in good agreement with the value 0·016″ obtained from the law connecting luminosity with period in Cepheids That of Betelgeuse is also 0·014″, which is near the mean of other determinations. For α Centauri and 61 Cygni the values found were 0·770″ and 0·300″, but these are more a check on the graduation of the curves than of the parallaxes themselves.

THE OLD BABYLONIAN VENUS TABLETS —A note in these columns more than a year ago described Dr. Fotheringham's work in dating these tablets, which are an important source for early chronology. Father Kugler was the first to deal with the problem, and fixed on the dates −1800 to −1780 for the series of observations contained in the tablets. Dr. Fotheringham made the dates 120 years earlier (they must be shifted by multiples of 8 years, owing to the fact that both Venus and the moon nearly repeat their positions relatively to the sun after this period). Dr. C. Schoch has lately been visiting Dr. Fotheringham at Oxford, and has just published a pamphlet entitled "Ammizaduga," which makes a further alteration in the dates, making them −1856 to −1836. One difficulty in the research is the question of intercalary months, with regard to which Ammizaduga appears to have changed the system. Light is thrown on them by study of the tablets relating to the harvests of dates and barley, as these give an indication of the position reached by the sun. It is claimed that, taking all the circumstances into account, the dates now adopted are the only ones that satisfy all the data. The mean dates of Nisan 1 reduced to Julian reckoning are given as follows:

Year	0	Nisan 1 =	
,,	−1000	,,	Mar. 30, 1 day before equinox.
,,	−2000	,,	Mar. 29, 9 days ,, ,,
,,	−3000	,,	Apr. 1, 14 ,, ,, ,,

Research Items.

PHYSICAL CHARACTERS OF SERBIAN GYPSIES.—Dr Viktor Lebzelter has recorded in the Journal of the Gypsy Lore Society, Ser. 3, vol 3, Pt 4, the results of anthropometric observations made in 1916 on forty-five Serbian gypsies who were prisoners of war. Gjargjevič has classified the gypsies of Serbia into three strata, of which the first and third are Moslems and the second Christian—Rumanian gypsies who with the other Rumanian inhabitants of Serbia entered the country in the seventeenth century. The subjects of Dr Lebzelter's observations belonged to the Christian stratum, though only seven called themselves Rumanian gypsies. They came from north-west Serbia and all were sedentary. They were remarkably homogeneous. Their hair was thick, and smooth like that of Hungarian and Bosnian gypsies. In the majority of cases it was black, but ranged to light brown. The colour of the iris in eighteen cases was dark brown, but black-brown, brown, greenish-grey, brownish-grey, and greenish-brown also occurred. The average height was 1627 mm.; 24 per cent. were tall or very tall The cephalic index ranged from 72·49 to 88 76, the average being 78·3 From an analysis of published measurements of Balkan gypsies, 952 individuals, Dr. Lebzelter concludes that the original type is dark, smooth-haired, moderately short, mesocephalic, moderately hypsicephalic, leptorhine, and perhaps leptoprosopic. The Serbian gypsies show this original element more clearly than the Hungarian gypsies

TRIBES OF THE GRASSLAND AREA, CAMEROON.—Capt L. W. G. Malcolm has contributed to *Mitt Anthrop. Gesellschaft in Wien*, Bd. 55, a detailed study of the physical anthropology of the Eyap tribe of the Central Cameroon. The observations were confined to males, forty-four measurements being taken on each of one hundred individuals between the ages of twenty and fifty years out of a total adult male population of not more than 700. Five albinos with eyes hazel to green in colour were seen, and *leucoderma* on hands and legs is common in both sexes. Deformations include elongation of the head, the infant's head being moulded by the mother soon after birth, moulding of the nose, piercing of ears, lower lip, and septum of the nose, chipping of the teeth, circumcision, cicatrisation, and tatooing. The ratio of males to females is 25·92 per cent The rate of infant mortality is high, and the number of children in polygamous families low. The head-chief, with more than 100 wives and concubines, had twenty-five children, of whom only five were living. Other chiefs with wives numbering between twenty and fifty had even fewer, and in nearly all cases there are more children by monogamous marriages. The maximum head-length recorded is 205 mm., the minimum 180 mm., the mean cephalic index 79·37. While the Eyap are mesaticephalic, according to the usual classification, they show a strong tendency to brachycephaly.

THE RELATIVITY OF TIME.—An article in the February issue of *Scientia* by Prof. F. Severi of the University of Rome deserves the attention of all who are interested in the philosophical aspect of the principle of relativity. It is an examination of objections of a general kind to the relativity of time. The argument deals with three objections to Einstein's definition of simultaneity: "Two flashes produced at equal distances from me are simultaneous if I perceive them at the same instant." The first objection is that the definition depends on a concept of simultaneity which is spontaneous and intuitive, the very concept the definition seeks to get rid of. The second is that logically the definition is circular, for it presupposes that the light reaches me from the two places at which the flashes are produced in equal times, whilst I can only measure intervals of time if I already possess the notion of simultaneity. The third is that the hypothesis of the independence of the velocity of light of the motion of the source and of the observer is *a priori* untrustworthy, because it precludes our thinking of a light phenomenon in the concrete, that is, as a phenomenon arising, developing, and finishing within its own environment. Prof. Severi, in replying to these objections, concludes a very lucid argument with the opinion that, so far from the principle of relativity having, as some have claimed, removed the last anthropomorphic vestiges from science, absolute time is both egocentric and anthropomorphic, and, however we regard the universe, whether as a reality external to us or as the projection of a construction of our mind, the maxim of Protagoras remains profoundly true: man is the unity of the measure of the universe

DIFFERENTIATION OF BREEDS BY SEROLOGICAL METHODS.—The *Journal of Immunology* (vol 9, No 6, November 1924) contains a paper by W Bialosuknia and B Kaczkowski, of the Institute for Serological Research and the Animal Breeding Department of the Institute for Agricultural Research in Poland, on the problem of determining the descent of certain breeds of sheep by applying the methods previously adopted by Londsteiner and others in their researches on the isoagglutination of blood among races of men. The sheep employed in the investigation were South-downs, a local Polish breed, a mountain breed from the Carpathians and Karaculs. It was definitely shown that whereas certain types of erythrocytes are agglutinated by all the sera having the capacity for agglutination, others are only agglutinated by certain sera, and that the sheep investigated fell readily into groups according to the results of the isoagglutination test It was impossible, however, to distinguish the breed of sheep by this test, since the same groups were present within the various breeds. Nevertheless, evidence was obtained of the existence of serological characteristics which could be transmitted in accordance with Mendelian expectation It was found, moreover, that external factors played no part in the phenomena of isoagglutination The authors are pursuing the subject further

HERRING INVESTIGATIONS.—The report for 1923–24 of the Dove Marine Laboratory, Cullercoats, Northumberland, drawn up by Prof Meek, contains an account of a large amount of work Following up his researches on herrings Mr B Storrow, who for many years has made this his speciality, contributes a detailed paper on herring shoals in which he reports on more than 7000 examples from various localities. He finds that those from the Smalls and from St. Ives were of mixed growth and practically all mature, making it difficult to fix separate races From examination of the scales of the various herrings he makes the suggestion that the larger growth variations, as indicated by these scales, are to be interpreted as representing periods of migration to or towards areas of greatest growth which are oceanic, and he concludes that in the case of the North Sea herrings, a northerly migration is necessary to bring about a more rapid increase in size. Mrs. Cowan adds a report on the size of the herrings showing that various shoals of different sizes and ages appear at different times.

EXPERIMENTS ON ECHINODERMS.—The report for 1924 of the Marine Biological Station at Port Erin,

Isle of Man, by Prof. Jas. Johnstone, states that most of the research done at that laboratory has been published elsewhere, the amount of this work showing abundant activity on the part of the staff. In the appendix, however, there are two interesting papers, one by Mr J. Ronald Bruce, naturalist of the Port Erin Station, on the seasonal and tidal P_H variation in the waters of Port Erin Bay, and one by Mr H. C. Chadwick, research zoologist, entitled "Natural History Notes," in which he gives some recent plankton observations and describes some very interesting experiments on the vitality of the spines and pedicellariæ of echinoderms from detached portions of the test. It is shown that these may still respond to stimuli after thirteen days, and pedicellariæ alone when detached from the test may retain their vitality almost as long as when *in situ*. With regard to the unnamed larva figured in these notes, there seems no doubt that it is the free-swimming cercaria of the trematode *Pharyngora bacillaris*, which is to be found fairly commonly in the Channel in the winter months and is conspicuous in having an annelid-like tail regularly provided with setæ. The intermediate host may be a medusa or a ctenophore, in which it lives freely without encystment, and the final host is the mackerel. The parasitic ciliate protozoon *Cryptochilum boreale* in *Echinus esculentus*, from the Shetland Islands, recently described by Mr C. C. Hentschel, is found to be common in the Echini from Port Erin.

POLLEN DEVELOPMENT IN SWEET PEAS.—The extensive genetical studies of *Lathyrus odoratus* by Bateson, Punnett, and others make a critical investigation of the cytology of this species desirable. In a preliminary account of such a study (*Brit. Journ. Exptl. Biol.*, vol. 2, p. 199), Miss J. Latter describes some of the features of the pollen development. The haploid chromosome number is already known, from the work of Winge, to be seven. In the second contraction stage of meiosis, the spireme is thrown into seven radiating loops, and for this stage Prof. Gates suggests the term broxonema. Each loop consists of a pair of chromosomes end-to-end. When the thread is still very slender the arms of the loop are frequently twisted about each other near the base. This would provide a possible basis for crossing-over combined with telosynapsis. Hitherto crossing-over has only been described in connexion with parasynapsis or a side-by-side pairing of chromosome threads. The view is also expressed that the linin rather than chromatin is the probable basis of inheritance.

ANIMAL ATTACKS ON LEAD TUBING.—At the Linnean Society on March 5, Mr Gerald Loder showed a piece of lead piping from Waterloo Station, London, gnawed by rats. "The general opinion was that the rodents gnawed the metal in order to wear down their teeth, and not to reach the water or to enlarge a passage-way." The destruction of lead tubes by animals is also discussed by Prof. R. Hesse of Bonn in the *Biologisches Zentralblatt*, Part 1., for 1925. He here explains the action of the rats in gnawing through a tube of 4 mm. thick as due to their endeavour to penetrate from a cellar into a basement, an endeavour which a stream of water from the pierced pipe would presumably throw considerable cold water upon. Dr. Hesse describes other examples of metals being attacked; thus in Shanghai species of Xylocopa eat through the lead sheath on telephone cables, although it is 0·8 mm. thick. The correspondent of a cable company explains that these "wasps" mistake the cables for bamboos and bore the holes in order to deposit their eggs therein! As soon as a rough "twine braiding" is wrapped round the smooth cable, it no longer has attraction for them and they leave it alone. The same cable firm reports the penetration of a submarine cable, armouring, jute and lead sheath, by chitons, which had slowly penetrated even the lead tube presumably by the slow chemical action of acid substance excreted from the foot.

THE SARCOPT OF THE BUFFALO.—T. M. Timoney gives an account in Bull. 154, Agric. Res. Inst., Pusa, 1924, of the bionomics of this parasite as observed at Muktesar. The average number of eggs laid by a female under experimental conditions was 17 to 18, and ten days was the maximum duration of life of an egg-laying female. The incubation period of the eggs is 1 to 2 days at summer temperature, and 2 to 3 days in winter. The interval between hatching from the egg and attaining adolescence is 6 to 8 days. The ovigerous and pubescent females can withstand better than the other stages separation from their host. The author records tests with 10 per cent. creosote in olive oil, which suggests that it may be found effective in controlling this sarcoptid.

TEXTURE AND STRUCTURE.—In the *Geol. Fören. Forhandl.* Bd. 46, Dec. 1924, pp. 654-660, P. J. Holmquist summarises the different definitions and usages of the petrographic terms "texture" and "structure". There is more diversity of opinion with regard to the latter term than to the former. Iddings, for example, applies "structure" to features due to fracture, aggregation, or erosion, whereas many Continental petrologists have used the term in the Anglo-American sense of "texture", that is, to connote the manner in which the internal units of a rock are arranged. Holmquist suggests that the confusion be brought to an end by accepting the meanings given by Holmes in his recent "Nomenclature of Petrology," these being also the meanings that have long been adopted by Tornebohm and other Swedish petrologists. "Structure" is thus applied to the appearance of a composite aggregate which is itself made up of simple aggregates, and each of the latter has a "texture" due to the degree of crystallisation, the grain size, and the shapes and interrelations of the crystals or other constitutional units.

EQUIPMENT FOR ARCTIC EXPEDITIONS.—The plans of the *Terra Nova* and a detailed list of its equipment and stores during its employment with Captain Scott's expedition form one of the most recent publications of the British Antarctic Expedition (1910-13) (London: Harrison and Sons, London. 5s. net). The publication, which is edited by Col. H. G. Lyons and is entitled "Miscellaneous Data," contains also some notes on equipment and transport animals which should prove useful to expeditions of the future. It is of interest to note that the mules used by the search party in 1912 seemed far better suited to the Antarctic conditions than the ponies which Captain Scott used in the earlier stages of his southern journey. They were Indian pack-mules trained for snow work in the Himalayas. The volume also includes a short note on the tidal observations.

MOVING RAINBOWS.—In NATURE of Dec. 13, 1924, p. 860, Mr. G. B. Deodhar described some interesting observations made by him of a double and mobile rainbow. Mr. G. Fergus Wood, of the Forest Research Institute, Dehra Dun, writes to say that he happened to witness a somewhat similar phenomenon a year or so ago. He says: "I had just taken some readings with a theodolite in the early morning when an incomplete rainbow appeared in the sky above the point which I had been observing. The sky was clear, with the exception of a few clouds in the neighbourhood of the shower responsible for the bow. I elevated the telescope to look at it; as I did so the bow began to move rapidly out of the field of view so that I had

to depress the instrument to follow it. The movement was about 3°. I could detect no change in colour sequence or in radius, though the final bow seemed brighter and was complete The movement lasted less than thirty seconds" Mr. Wood does not agree with Mr. Deodhar's explanation of two bows appearing in the sky close together and with the same colour sequence. He remarks. "I am inclined to attribute both phenomena to either a reflection or refraction of the sun's rays before entering the rain, or to a reflection (unlikely) or refraction between bow and observer The latter—in the nature of a mirage effect—seems to me the most probable, since the time was favourable and magnification is frequently the result of mirage"

THE THEORY OF STRIATED DISCHARGE.—An explanation of the mechanism of the striated discharge, based on recent investigations of collisions between electrons and atoms, is given by Prof A. Günther-Schulze in the *Zeitschrift fur Physik* for February 11 He shows that in many gases, even when the collisions are inelastic, the velocity of the electrons, which move irregularly in all directions, increases in an electric field up to a definite maximum value He gives the law which governs the velocity at different distances from the cathode, where it is zero If the velocity expressed in volts is less than the excitation voltage of the gas, the losses on collision with the atoms will be small, and there will be no luminosity, when, however, the velocity reaches this point, the energy of a colliding electron will be given up to the atom, which will emit light This will take place at a definite distance from the cathode, and the first bright stria will be produced, the velocity of most of the electrons being reduced to zero It is known that faster electrons are not so likely to produce excitation as those that have the excitation velocity, and most of the former will pass on into the succeeding dark space, where they will not produce luminosity. The same is true of the electrons which have been brought to rest in the first stria, which will gradually acquire velocity as they pass through the dark space, and will excite the atoms in a second narrow zone when they have acquired the correct velocity

THE ABNORMALLY LOW VOLTAGE ELECTRIC ARC — Dr. R. Bar describes experiments with mercury vapour, argon and helium in the *Zeitschrift fur Physik*, February 19 With mercury the smallest excitation voltage ($1S - 2p_3$) is 4·7 volts, and the voltage corresponding to the resonance line 2537 Å U ($1S - 2p_2$) is 4·9 volts; but Hebb found that an arc would burn with 1·7 volts and Yao with 1·8 volts. The author's experiments were directed towards finding whether such low voltages would suffice when there were no oscillations in the current and voltage, and his result was that the lowest steady voltage which would give an arc was 2·25 volts Previous experiments by Bär, v Laue and Meyer have shown that the arc produced in helium, at 8 volts, by Compton, Lilly and Olmstead was due to oscillations in the voltage, the peak voltage rising above the critical value 19·8 volts. The author has now succeeded in producing an arc in helium with a steady voltage of 16·5 volts, using specially purified helium and a very hot cathode wire.

A SUGGESTED EXPLANATION OF THE QUANTUM THEORY.—M. L. de Broglie, in the *Annales de Physique* of January-February, assumes the existence of a periodic phenomenon, the exact nature of which has still to be determined, which is connected with every isolated "portion of energy," including electrons, protons, matter in general, and quanta of light and X- and γ rays. The fundamental idea of the theory of quanta is the impossibility of considering an isolated quantity of energy without associating with it a certain frequency, in accordance with the equation $E = h\nu$, which must be connected with the mass of the energy portion, or mobile, by the Planck-Einstein equation. Considering the question in the light of the relativity theory, it is found necessary to associate with uniform motion of a material point a certain wave propagated from it, the phase of which is displaced in space with a constant velocity greater than that of light. In the more general case of an electrically charged body, moving with variable velocity in an electromagnetic field, it appears that the principle of least action in the form given by Maupertuis, and Fermat's principle of concordance of phase, may be two aspects of a single law. The known laws of quantified trajectories can be interpreted as expressing the resonance of the phase wave along the length of closed or quasi-closed trajectories, this appears to the author to be the first physically plausible explanation proposed for the Bohr-Sommerfeld stability conditions The theory leads to a real harmony between the views of Newton and of Fresnel; but it is shown that the electromagnetic theory requires revision, though as a statistical approximation the existing theory is perfectly satisfactory in a very large number of cases The scattering of X- and γ rays, statistical mechanics, and the law of radiation of a black body are dealt with in accordance with the new theory

HOLMIUM.—F H Driggs and B S Hopkins describe in the February number of the Journal of the American Chemical Society some work carried out on holmium Holmium and yttrium were separated from erbium by fractional crystallisation of the bromates, yttrium was removed by thermal decomposition of its nitrate The ratio of holmium chloride to silver was determined, the results giving a mean value of 163 47 for the atomic weight of holmium.

THE CALOMEL ELECTRODE.—A method of preparing calomel directly in saturated potassium chloride solution is described by W W Ewing in the Journal of the American Chemical Society for February A current of 1·3 amp /dcm.^{2} at 35-40 volts was applied to the system Hg^+ KCl(sat) *N* KCl $CuCl_3$(sat) Cu^-. Calomel mixed with potassium chloride crystals and finely divided mercury collected on the mercury surface, which was continually scraped with a stirrer This method is less tedious than the older one, and the product is shown to be a dependable standard for use in the calomel electrode.

THE HABER EQUILIBRIUM.—It has recently been found that the equilibrium constant of the Haber equilibrium (hydrogen, nitrogen and ammonia) is a function of pressure, and it follows that such data can be used, at least in principle, to test assumed forms of the mass action law. Existing data must be supplemented with hypotheses, however, enabling us to pass from the properties of pure gases to those of mixtures; and L J Gillespie, in the February number of the Journal of the American Chemical Society, points out that the rule of Lewis and Randall for calculating the fugacity of a gas in a mixture offers a suitable hypothesis, provided it is made exact by the addition of a certain supplementary term based on the assumption that at large volumes the equilibrium pressure is equal to the ideal-gas partial pressure. The author shows thermodynamically that the three propositions—exactness of the modified fugacity rule, additivity of volumes and additivity of heat content—all follow from any one of the three. An experimental method is outlined for testing the author's results.

Submarine Measurements of Gravity.

RECENT years have witnessed great advances in our knowledge of the gravitational field near the earth's surface on land, but in spite of many efforts the extension of these determinations to oceanic regions has until quite lately proved a very intractable problem. It would now seem that substantial success has at last been achieved, as the result of trials of a specially designed apparatus and method during a voyage of a submarine from Holland to Java in 1923. The apparatus used is a development of one which was devised to overcome difficulties experienced in ordinary pendulum determinations in Holland, where the unusual mobility of the soil had made it impracticable to eliminate slight movements of the supports. These motions were rendered innocuous by suspending from the same plate several pendulums, having very nearly equal periods of vibration, and causing them to vibrate in different phases The success of this device led to its trial at sea also, on a steamer of 1200 tons, but the weather was bad and the pitching and rolling of the vessel spoilt the attempt. Prof. van Iterson, Director of the Netherlands State Mines, then suggested that these disturbances might perhaps be avoided, or sufficiently reduced, by making observations on a submerged submarine instead of on a floating vessel Preliminary trials confirmed the value of this proposal and arrangements were then made for a more exhaustive test.

Dr. Vening Meinesz, who was responsible for the investigation, has recently published a provisional account of the work.[1] The apparatus (made by Stuchrath) consisted of two pairs of pendulums suspended from the same plate, oscillating in opposite phases, two by two in planes at right angles Their oscillations were recorded photographically. The pendulums were of brass, which led to difficulties in connexion with their large temperature corrections, since the temperature in a submerged submarine quickly rises; invar pendulums could not be used because of their susceptibility to magnetic fields, which are scarcely avoidable in a submarine. Dr. Meinesz suggests that errors arising from this source should be reduced in future experiments, either by the use of quartz pendulums, or by shielding the instrument from changes of temperature. The apparatus was mounted on a large wooden stand, which was not so firmly fixed as not to require watchful guard against shocks It was placed as near to the metacentre of the submarine as possible.

Successful experiments were made in the Mediterranean and in the Indian Ocean. The pendulums were swung for periods of fifteen to twenty minutes, but rather longer periods, up to thirty or forty minutes, are recommended in future work. The various sources of error are discussed by Dr. Meinesz, who concludes that the mean error of a determination of the time of oscillation of a pair of pendulums in calm weather was 2 to 3 units of 10^{-7} second, and in rough weather, with the submarine at a depth of 20 or 30 metres, about 10×10^{-7} second

This work by Dr Meinesz was recently described by Colonel Lyons at a Geophysical Meeting of the Royal Astronomical Society, and it was urged that similar work should be carried out by other countries. Sir Gerald Lenox Conyngham discussed the results obtained (in Dr. Meinesz's provisional report this is not done, nor is any chart or topographical description of the observation points given, except latitude, longitude, and the depth of the ocean) The observed values of gravity far out at sea differ sufficiently little from the computed normal values to indicate that there must be isostatic compensation. Near land the compensation seems to be less complete, and it was stated that Dr. Meinesz infers a greater extension of the compensating layer below the mainland than is required by the theory of isostasy.

[1] "Observations de Pendule sur la Mer pendant un Voyage en sous-marin de Hollande à Java, 1923." Publication Provisoire par Dr F. A. V. Meinesz.

Factors influencing Growth in Trees and Plants.

THE Carnegie Institution of Washington has recently published the results of a further very interesting series of investigations on growth in trees and massive organs of plants[1] Prof D. T. MacDougal's dendrographic measurements provide considerable additional information on the behaviour of tree-trunks. The investigations, which were conducted chiefly on conifers, but also on broad-leaved species, cover the duration of the growing season, seasonal activity, the increase of wood and of roots, the path and rate of movement of liquids in stems and the general use of the dendrometer for measuring the yearly increase in the circumference of stems. In addition, auxographic records are obtained of the growth of Opuntia stems and flowers, Mesembryanthemum leaves, potato tubers, and the fruits of Cucurbita The experiments were conducted principally on plants grown in the open and under the full influence of their habitual environment so that the normal activity of the plants was not disturbed. Amongst the interesting conclusions to which Prof. MacDougal directs attention in his summary the following may be noticed.

In the investigations on the Monterey pine (*Pinus radiata*), it is observed that the duration of seasonal growth is longest in young trees, whilst wide differences are exhibited by older trees. The thickness of the woody layer shows a general correlation to the length of the growing season but no constant relation to the total amount of rainfall; it is more likely to be due to the favourable conjunction of a number of factors in which seasonal relative humidity may be an important agent. The flow of solutions, as shown by the use of dyes, is found to be much greater late in the season than in the stage of rapid growth, and confirmation is obtained that the sap travels chiefly in the wood of the two previous years Several other interesting associations of facts in connexion with the movement of liquids and variation in girth of stem are also recorded.

In general, it is found that practically all organs or members tested with the dendrograph show daily equalising variations in size and volume in direct relation to their water-balance, and that these daily equalising variations are characteristic of each species. Further, the results of these investigations show that the amplitude of the daily variation is not dependent upon the softness of the wood and the character of the bark.

The development of potato tubers, as recorded by auxographic apparatus, shows that the period of enlargement may be estimated at 90 to 100 days, and that their behaviour is comparable to that of nuts and fruits.

The second part of the bulletin contains Dr. Forrest Shreve's records on the growth of trees. A series of

[1] "Growth in Trees and Massive Organs of Plants Dendrographic Measurements," by D T. MacDougal "The Growth Record in Trees," by Forrest Shreve (Publication 350.) Pp. 116. (Washington: Carnegie Institution, 1924) 1.50 dollars.

detailed analyses of stems of different ages and a consideration of the results obtained of growth in relation to rainfall and temperature lead to some very interesting conclusions. Examination of trunks of pine and redwood shows that the annual rate of growth is not the same at the stump and at different heights in the trunk, and that it is greater toward the centre than towards the periphery. No definite correlation is found between growth and rainfall and growth and temperature, and the conclusion drawn is that the annual growth of the specimens examined is dependent on the general complex of environmental conditions and not on any one particular factor.

A further contribution to this study has recently been published in the Journal of the College of Agriculture, Hokkaido Imperial University, Sapporo, Japan.[1] The experiments, which took place in the University Botanic Garden at Sapporo, were conducted to show the influence of meteorological factors on the growth of trees, or, more precisely, on the girth of the trunk. Prof. Hirokichi Nakashima was fortunate in being able to select a healthy young specimen of *Abies Mayriana*, about 50 years old, which was growing a convenient distance from a meteorological station

Until recent years it was supposed that the girth of the stem increased continually from spring to autumn, and that in winter during the resting period the girth remained unaltered The experiments, however, showed that even in winter appreciable increase and diminution in girth took place, depending chiefly on meteorological factors. In fact each cycle of development may be divided into four periods During the vegetation period, from the end of April to the end of October, precipitations proved the most important factor. The relations between transpiration and absorption were the determinants through the autumnal transition period, the month of November, and the late spring period March and April During the resting period, from mid-December to the beginning of March, the temperature of the air was the chief factor. Prof. Nakashima has been able to express these relations in formulæ The conclusions drawn are that increase in girth depends either on growth or on the swelling of water-containing tissue; changes in girth are connected with transpiration and absorption; increased transpiration without corresponding water-absorption by the roots causes decrease in girth; prevention or reduction of transpiration during absorption causes swelling of the stem, and, generally, increase and decrease of girth are closely connected with meteorological conditions

The article is accompanied by the daily meteorological observations and experimental records of the whole period of five years during which the experiment lasted The apparatus used for measuring the varying size of the stem was Friedrichs Zuwachs-autograph

Published by the University, Sapporo, November 1924

Haddock Biology.

THE first part of a paper on the biology of the haddock, by Mr. Harold Thompson, was referred to in NATURE, August 30, 1924, p. 333. The second part, on the frequency and distribution of the age classes in 1923, which has recently been issued,[1] gives an account of later investigations. In the first part it had been shown that the year 1920 had produced a remarkably large brood of young haddock, which in 1922 were beginning to show in the commercial catches as two-year-old fish. We now learn that in 1923, as Mr. Thompson had ventured to predict, these fish had become the mainstay of the North Sea haddock market, and that they constituted 70 5 per cent. of all the haddock captured, so far as these were sampled.

The years 1921 and 1922 were both failures so far as the young brood of haddock in the North Sea was concerned, but it is pleasing to note that 1923 was one of the best years on record If all goes well with the brood, these fish should become prominent in the commercial catches in 1926 as three-year-old fish Mr. Thompson was able during 1923, by a detailed study of the scales of this group of haddock, to establish still more closely the relation between the growth of the scale and the growth of the fish He shows that the scales first formed on the fish are those which lie immediately below the third dorsal fin, and if scales from this position in older fishes are selected for examination, it will be found that the length of the fish at the end of each growth-year can be determined correctly on the assumption that the growth of the fish is directly proportional to the growth of the scale On the other hand, scales from below the second dorsal fin will give a calculated result about half a centimetre short, and those from below the pectoral fin 2 75 cm short This is an important point to have established and will clear up many of the difficulties which those working at problems of the growth-rate of fishes have encountered.

Further observations are recorded on haddock from Iceland, the Faroes, and from the Norwegian coast. The rate of growth of Iceland and Faroe haddock appears to be much greater than that of North Sea fish, but in Iceland the rate decreases from the south coast, by west and north to the east coast, where it is smallest. Good survival years for the brood at Faroe, Iceland, and Norway differ from each other and rom those of the North Sea

University and Educational Intelligence.

ABERDEEN.—At the graduation ceremony held on April 1, the degree of D.D. was conferred on the Right Rev E W. Barnes, F R S., Bishop of Birmingham.

LONDON.—The two following courses of free public lectures at King's College are announced: "Problems of Modern Physics," Prof. W Wien, on April 21, 22, and 23; and "Recent Advances in the Study of Living Cells," Prof. R Chambers, on April 27, 28, and 29. The lecture hour in each case will be 5 30

THE Council of the University College of Southampton is to award two open exhibitions in engineering to candidates who may or may not be now resident in the district. The awards will be made on the recommendation of the Engineering Faculty Board without formal examination, provided the candidates have matriculated and are prepared to read for a degree in engineering

THREE open scholarships, each of the yearly value of 40*l*., some bursaries of 20*l*., and others covering the tuition fees in commerce are being offered in competition by University College, Leicester. The examination will be held at the College in June. Particulars may be had from the secretary.

IF industrial prospects in Great Britain are at present clouded, good progress can be recorded in

the direction of improved social service The activities of the Carnegie United Kingdom Trust, as set forth in the eleventh annual report, may be summarised as an attempt to restore to the English people the amenities of life which their forefathers enjoyed, and of which they were deprived by an over-rapid development of the factory system The library policy of the Trust has, as is well known, been directed to the provision of facilities for reading in the rural districts by the establishment of County Library schemes reinforced by Central Loan Collections Grants for the establishment of County Libraries have now been made in eighty-six counties in the United Kingdom of Great Britain and Ireland, and in the course of a few years these will all be on an independent basis The development, however, of the Central Loan Collections on self-supporting lines presents many difficulties The cost of the administration of these national book stores is likely to increase more rapidly than the income from the contributory libraries, and it is clear that in the long run some assistance will have to be provided by the State In the meantime the grant to the London Central Library has been increased from 1000*l* to 3000*l*, at which sum it will be maintained for the next four years Other activities of the Trust in the direction of fostering the national talent in musical composition, the drama, and folk-dancing continue to show satisfactory results The Margaret Carnegie Hostel for girls at Portree was officially opened last October, and a large grant has been made for the purchase of a building in East London to be used as a hostel for boys

VISUAL Education Departments in Educational Institutions form the subject of a report published in Bulletin, 1924, No 8 of the United States Bureau of Education. Of 78 State universities and State colleges, 20 have departments sufficiently well organised to employ special officials to handle visual aids. They are generally organised as parts of the university extension divisions of these institutions, but the work is not entirely extra-mural, and the departmental heads attend faculty meetings The growth of these departments is described as a teacher movement and not a commercial development on the contrary, it is a development in despite of the commercial exchanges, which have sided with the theatres in their opposition to supplying films to educational institutions Five departments undertake the actual production of films. Columbia University has a course in moving-picture production, and the University of Nebraska is said to have built a 20,000-dollar moving-picture studio on its campus. The University of Wisconsin has purchased the negatives of a large group of educational films, and sells the prints direct to other institutions at about 60 dollars per reel of 1000 feet—considerably less than what commercial firms charge The United States Department of Agriculture and the Bureau of Mines have done much to popularise instruction in agriculture and in mining and metallurgy by the use of films and slides The Bureau of Mines contrives to produce films without any expense to the Government beyond the salary of an engineer, who assists in planning and directing the work to assure its being worthy of circulation, the whole of the rest of the cost of production and making the copies being borne by the industries filmed. Colleges, high-schools, and churches are the largest users of these films. Though films figure largely in the report, they are by no means universally considered the most useful of visual aids The slide has a decisive majority vote for usefulness Much use is also made of stereographs and exhibits of objects from museums.

Early Science at Oxford.

April 13, 1686. A discourse concerning Hydraulic Engines, drawn up by Mr King of Dublin, was communicated by Mr. Ash: the Society ordered their thankes for this ingenious discourse, both to Mr Ash, and Mr. King.

Mr Caswel communicated a Mathematicall paper containing the Solutions of severall problemes, composed by Mr. Baker of Bishops Nymton in Devonshire

April 14, 1685 Mr President communicated a farther discourse concerning ye Air's Gravity observed in ye Baroscope, occasioned by that of Dr. Garden read ye last meeting He also comunicated ye following observation, that at Dover, on March 19 last past, (which was two daies after the last quarter of ye Moon) there was observed this extraordinary in ye Tide. After it had flowed some time, it ebbed two foot, then flowed again, and then ebbed, and after flowed a third time, and so a fourth time: so that there were four flowings, and three ebbings in one Tide

A Letter from Mr Cony, dated Rochester March 27, was read concerning the raining of Fish, as it was supposed to have been in that countrie some time since.—Mr Cole of Bristoll mentioned a substance proceeding from Calamy oar, which far exceeds, in colour and finenesse, all metalls, beside gold, and silver

April 15, 1684. Mr. Pulleyn informed ye Society, that an Elm, split at Cumnor, during ye late frost, was observed to have Ice in it It was affirmed that vines have been split this winter, more frequently towards ye South, than any other, point of ye compass, and that they split more in ye Thaw following ye great Frost, than in ye frost itself. ye reason of ye former may be, because vines lye most open to ye South, and partly also (as Mr Walker imagins) because ye sap-vessells are largest, and ye quantity of ye sap greatest in ye south side of ye vine, as in other Trees. Dr. Smith did himself observe, that ye Cedars of ye Physick garden, raisd from seeds brought out of Syria, bore ye shock of ye frost, without being any way damaged. Mr. Crouch was desired to enquire, whether ye Cedars of Balliol College were any way injured A Letter dated April 10th, from Mr Aston, Secretary to ye Royall Society, was read, which questioning whether a body, in shape like ye heel of a Shooe, presented by my Lord Bishop of Lincoln, to Dr. Plot, being esteemed as a Petrification of leather, be any thing more then a bare Incrustation. For ye satisfaction both of ourselves, and ye Royal Society, it was ordered, that this (supposed) Petrification should be examined, as to its make, and texture; more especially by boring it Mr. Wm Piggot tooke this charge on him.

Three papers of Dr Lister's concerning thunder &c proceeding from Pyrites, and a letter from Sir R Southwell concerning ye compasses of a Ship being changed by lightning, were read.

A Peice of black Brittish Marble, spotted white, found in ye grounds of Mr Wogan of Bolston in Pembrokeshire (who uses this sort of stone for ye makeing lime) was comunicated to ye Society, by Dr. John Floyd, Vice-chancellor of ye University. It was ordered to be put in the Ashmolean Museum. This led us to discourse of sawing marble. It was affirmed by Mr. Wheeler that Little Veins, called *pins* by ye stone-cutters, run up and down, and are sometimes so many and so hard, that they dull ye teeth of ye tooles, so that many times it is not worth ye while to worke ye stone.

Societies and Academies.

LONDON.

Royal Society, April 2.—H. E. **Armstrong**. Studies on enzyme action, xxiii. The oxidase effect and the phenomena of oxidation in general. carbonic oxide.—N. K. **Adam** and G. **Jessop**. An explanation of the so-called "intertraction phenomenon" between solutions and the molecular significance of negative surface tension. Solutions mix by sending out streamers into each other only (1) if they are superposed, and (2) if there is a difference in rate of diffusion between the dissolved substances. The streamers are due to the different rates of diffusion between the two liquids disturbing the hydrostatic equilibrium of the layers. Capillary forces are not concerned. The movements are entirely different if (1) the faster, (2) the slower, diffusing solution is superposed. With these restrictions the phenomenon seems to be general, but it involves no unknown forces. "Negative interfacial tension" means that the inward attractive forces which, when surface tension is positive, prevent molecules from escaping across the surface of the liquid, become negative. It is properly manifested in diffusion away from the body of the liquid.—Jane **Sands**. Investigation of oxidation in the blood of earthworms.—R. **Snow**. Conduction of excitation in the leaf of *Mimosa spegazzinii*. Simultaneous determinations were made of the velocities of the water current and of the excitatory conduction set up by cuts in the leaves. The latter is many times the more rapid. After the stimulus of a burn, conduction is much more rapid again. Excitation is conducted much more rapidly in the leaves of shoots totally submerged under water for several hours than in leaves attached to the plants in air. In very damp air the velocity of conduction in the leaf is increased to a less extent. Excitation is conducted down the leaf pinnæ with great acceleration, and this depends in part on the nature of the process of conduction itself. In the leaf of *M. spegazzinii*, excitation is regularly conducted by some mechanism that has nothing to do with the water current. Changes of pressure in the tube-cells play no part in conducting excitation, even in the leaf.—Dorothy **Adams**. Investigations on the crystalline lens. The lens resembles other tissues in possessing an autoxidation system made of two sulphur-containing components (*a*) water-soluble glutathione; (*b*) a thermostable protein residue. Experiments were made on fresh ox lenses, and oxygen uptake was measured directly and indirectly. Fresh lens has a definite oxygen uptake, evidently used for maintenance of its autoxidation system, since any alteration in concentration of glutathione in the lens causes corresponding change in oxygen uptake. The average glutathione content is higher than that of other more vascular tissues. The thermostable protein residue has no oxygen uptake; but with a few milligrams of glutathione it gives an oxygen-uptake curve exactly similar to that of fresh lens. Exposure of fresh ox lens to ultra-violet light or to heat rays causes measurable decrease in its glutathione content.

Royal Microscopical Society, February 18.—W. Bernard **Crow**: Variation in the hormogones of *Lyngbya nigra* Ag. The hormogones of the blue-green alga, *Lyngbya nigra* Ag., arise by division from the parent filament, the separation being effected by separation discs. Secondary separation occurs in the free hormogones, leading to the formation of very short hormogones. Some of the latter consist of a single segment only, but do not show the characters of spores. The separation discs, which are special deposits in the protoplasm, sometimes occupy a single segment. Ordinary transverse walls are occasionally absent at certain points in the trichome. Conjugations of adjacent segments in other Cyanophyceæ are interpreted as special cases of failure of transverse wall development.—W. L. **Roche**: Notes on the microscopic anatomy of the tentacular sense organ of *Cardium edule*. The siphonal tentacles of the common cockle are sensory structures, and some bear eyes and curious sense organs situated at the bases of ectodermal depressions. These "hair sense organs" occur on ocular tentacles, but may be on eyeless ones, in the former case the same nerve supplies both. These cells are club-shaped, but do not possess stiff hairs which project to the exterior. They give off fibrils which enclose the bases of the cells of the pit which themselves bear sensory hairs. This organ is probably connected with chemical sense.

Royal Microscopical Society (Industrial Applications Section), February 25.—The microscope in the textile industries. F. **Summers**. The microscope in cotton research. Two main lines of activity can be distinguished. (1) The morphological structure of the raw cotton hair itself is the object of investigation both in the natural condition and also after modification of its structure and properties by the action of chemical substances, as in various trade processes, such as mercerisation. (2) The search for the causes of the many defects—popularly known as faults—in cotton yarns and fabrics, which may be due to the presence of abnormal hairs in the raw material or to irregularities introduced during the various spinning, manufacturing, or finishing processes. The action of mildew upon cotton at every stage of manufacture is also productive of many defects, causing discolorations or, at times, actual decomposition. The study of methods for the prevention of mildew growth on cotton goods forms one of the main features of the botanical research.—T. B. **Bright**. Methods of examination of mildewed cotton material. In the majority of cases mildew is easily diagnosed, but occasionally, though the damage is considerable, there is very little fungus growth, and careful examination under the microscope is necessary.
